SURGERY

Scientific Principles & Practice

SIXTH EDITION

EDITORS

Michael W. Mulholland, MD, PhD

Frederick A. Collier Distinguished Professor of Surgery
Chair, Department of Surgery
University of Michigan
Ann Arbor, Michigan

Keith D. Lillemoe, MD

Surgeon-in-Chief
Chief, Department of Surgery
Massachusetts General Hospital
The W. Gerald Austen Professor
Harvard Medical School
Boston, Massachusetts

Gerard M. Doherty, MD

Surgeon-in-Chief
Brigham and Women's Health Care & Dana-Farber Cancer Institute
Moseley Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Gilbert R. Upchurch, Jr., MD

Chief of Vascular and Endovascular Surgery
William H. Muller, Jr. Professor of Surgery
Professor of Molecular Physiology and Biological Physics
University of Virginia
Charlottesville, Virginia

Hasan B. Alam, MD

Norman W. Thompson Professor of Surgery
Head of General Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Timothy M. Pawlik, MD, MPH, PhD

Professor of Surgery and Oncology

The Urban Meyer III and Shelley Meyer Chair for Cancer Research
Chair, Department of Surgery
The Ohio State University Wexner Medical Center
Columbus, Ohio

This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Contributors

David B. Adams, MD

Professor of Surgery
The Department of Surgery
Medical University of South Carolina
Charleston, South Carolina

N. Scott Adzick, MD

Surgeon-in-Chief
Children's Hospital of Philadelphia
C. Everett Koop Professor of Pediatric Surgery
Perelman School of Medicine at the University of Pennsylvania
Philadelphia, Pennsylvania

Gorav Ailawadi, MD

Chief, Section of Adult Cardiac Surgery
Associate Professor, Cardiothoracic Surgery and Biomedical Engineering
Director, Minimally Invasive Cardiac Surgery
Surgical Director, Advanced Cardiac Valve Center
Chair, VCSQI Research and Writing Committee
University of Virginia
Charlottesville, Virginia

Hasan B. Alam, MD

Norman W. Thompson Professor of Surgery
Head of General Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Shehab Ahmad Redha AlAnsari, MD

Resident physician
Department of Internal Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

Husain T. AlQattan, MD

Department of Surgery
Miller School of Medicine
University of Miami – Jackson Health System
Miami, Florida

Marjorie J. Arca, MD

Professor of Surgery–Pediatric Surgery and Pediatrics
Surgical Director of Pediatric Critical Care
Milwaukee, Wisconsin

Ali Azizzadeh, MD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Chad G. Ball, MD

Associate Professor of Surgery and Oncology

Department of Surgery
University of Calgary
Foothills Medical Center
Calgary, Canada

Thanh U. Barbie, MD

Instructor of Surgery
Harvard Medical School
Attending Surgeon
Brigham and Women's Hospital/Faulkner Hospital/Dana Farber Cancer Institute
Boston, Massachusetts

Bradley D. Beasley, DPM, CWS

Private Practice
Restoration Foot & Ankle, PLLC
Broken Arrow, Oklahoma

Adam W. Beck, MD

Assistant Professor of Surgery
Division of Vascular Surgery and Endovascular Therapy
University of Florida College of Medicine
Gainesville, Florida

Elizabeth R. Benjamin, MD, PhD

Assistant Professor of Surgery and Emergency Medicine
Division of Trauma and Surgical Critical Care
University of Southern California
Los Angeles, California

Christopher K. Bichakjian, MD

Professor of Dermatology
Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Timothy R. Billiar, MD

George Vance Foster Endowed Professor
Distinguished Professor of Surgery
Chair, Department of Surgery
University of Pittsburgh
Pittsburgh, Pennsylvania

John D. Birkmeyer, MD

Executive Vice President, Integrated Delivery Systems
Chief Academic Officer
Dartmouth-Hitchcock Health
One Medical Center Drive
Lebanon, New Hampshire

C. Richard Boland, MD

Chief, Division of Gastroenterology
Baylor Scott and White
Baylor University Medical Center
Dallas, Texas

Edward L. Bove, MD

Helen and Marvin Kirsh Professor of Cardiac Surgery
Chair, Cardiac Surgery Department
Cardiovascular Center

Ann Arbor, Michigan

Darren Bowe, MD

Attending Surgeon
Wyoming Medical Center
Casper, Wyoming

Robert S. Bresalier, MD

Professor of Medicine
Birdie J. and Lydia J. Resoft Distinguished Professor in Gastrointestinal Oncology
Department of Gastroenterology, Hepatology, and Nutrition
The University of Texas MD Anderson Cancer Center
Houston, Texas

Jonathan R. Brody, PhD

Director of Surgical Research, Professor
Department of Surgery
Thomas Jefferson University
Philadelphia, Pennsylvania

Carlos V.R. Brown, MD

Associate Professor
Dell Medical School
University of Texas at Austin
Trauma Medical Director
University Medical Center Brackenridge
Austin, Texas

David L. Brown, MD

Associate Professor of Surgery
Section of Plastic Surgery
University of Michigan
Ann Arbor, Michigan

Brandon R. Bruns, MD

Associate Professor
Department of Surgery
University of Maryland School of Medicine
R Adams Cowley Shock Trauma Center
Baltimore, Maryland

Steven R. Buchman, MD

M. Haskell Newman Professor in Plastic Surgery
Professor of Neurosurgery
Program Director, Craniofacial Surgery Fellowship
University of Michigan Medical School
Chief, Pediatric Plastic Surgery
CS Mott Children's Hospital
Director, Craniofacial Anomalies Program
University of Michigan Medical Center
Ann Arbor, Michigan

J. Kenneth Byrd, MD

Assistant Professor
Department of Otolaryngology – Head and Neck Surgery
Medical College of Georgia
Augusta, Georgia

Andrew M. Cameron, MD, PhD

Associate Professor of Surgery
Director of Liver Transplantation
The Johns Hopkins University School of Medicine
Baltimore, Maryland

E. Ramsay Camp, MD

Associate Professor of Surgery
Division of Oncologic and Endocrine Surgery
Medical University of South Carolina
Charleston, South Carolina

Darrell A. Campbell, Jr., MD

Professor of Surgery
University of Michigan
Ann Arbor, Michigan

Robert M. Cannon, MD

Instructor/Fellow
Department of Surgery
Division of Transplantation
University of Alabama at Birmingham
Birmingham, Alabama

Kenneth Cardona, MD

Assistant Professor of Surgery
Division of Surgical Oncology
Emory University Hospital Midtown
Emory Winship Cancer Institute
Atlanta, Georgia

Darrell L. Cass, MD

Associate Professor
Departments of Surgery, Pediatrics, and Obstetrics and Gynecology
Baylor College of Medicine
Co-Director, Texas Children's Fetal Center
Texas Children's Hospital
Houston, Texas

Paul S. Cederna, MD

Chief, Section of Plastic Surgery
Robert Oneal Professor of Plastic Surgery
Professor, Department of Biomedical Engineering
University of Michigan
Ann Arbor, Michigan

Rajiv Chandawarkar, MD

Director, Plastic Surgery, OSU East Hospital
Associate Professor of Plastic Surgery
Adjunct Associate Professor of Orthopedics
The Ohio State University Wexner Medical Center
Columbus, Ohio

Andrew C. Chang, MD

Associate Professor of Surgery
John Alexander Distinguished Professor
Head, Section of Thoracic Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Kristofer M. Charlton-Ouw, MD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Randall M. Chesnut, MD

Professor
Neurological Surgery, Orthopaedics and Sports Medicine
University of Washington
Seattle, Washington

Jayer Chung, MD, MSc

Assistant Professor
Michael E. DeBakey Department of Surgery
Division of Vascular Surgery and Endovascular Therapy
Baylor College of Medicine
Houston, Texas

Kevin C. Chung, MD, MS

Chief of Hand Surgery
University of Michigan
Charles B. G. de Nancrede Professor of Surgery
Section of Plastic Surgery
Department of Surgery
Professor of Orthopaedic Surgery
Assistant Dean for Faculty Affairs
University of Michigan Medical School
Ann Arbor, Michigan

Robert E. Cilley, MD

Professor of Surgery and Pediatrics
Penn State College of Medicine
Penn State Children's Hospital
State College, Pennsylvania

Damon Clark, MD

Assistant Professor of Surgery
Department of Surgery
Acute Care Surgery
University of Southern California
Los Angeles, California

Dawn M. Coleman, MD

Assistant Professor – Vascular Surgery
University of Michigan
Cardiovascular Center
Ann Arbor, Michigan

Dorin T. Colibaseanu, MD

Assistant Professor of Surgery
Section of Colon and Rectal Surgery
Department of Surgery
Mayo Clinic
Jacksonville, Florida

Zara Cooper, MD

Assistant Professor of Surgery
Harvard Medical School

Division of Trauma, Burns, and Surgical Critical Care
Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Bryan A. Cotton, MD, MPH

Professor of Surgery
University of Texas Health Science Center
Houston, Texas

Joseph Cuschieri, MD

Professor of Surgery
Director of Surgical Critical Care, Harborview Medical Center
Associate Program Director, Surgical Critical Care Fellowship
University of Washington
Seattle, Washington

Michael C. Dalsing, MD

Chief
Department of Surgery
Division of Vascular Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Kimberly A. Davis, MD, MBA

Professor of Surgery
Vice Chairman of Clinical Affairs
Chief of the Section of General Surgery, Trauma, and Surgical Critical Care
Yale School of Medicine
Trauma Medical Director
Surgical Director, Quality and Performance Improvement
New Haven, Connecticut

Jonathan D'Cunha, MD, PhD

Associate Professor of Surgery
Vice Chairman, Academic Affairs
Surgical Director, Lung Transplantation
Surgical Director, ECMO
Associate Program Director, Thoracic Surgery Program Director, Advanced Lung/Heart Failure Fellowship
Department of Cardiothoracic Surgery at UPMC
Pittsburgh, Pennsylvania

M. George DeBusk, MD, MSc, FACS, FCCP

Assistant Professor
Division of Trauma, Surgical Critical Care and Acute Care Surgery
UMass Memorial Medical Center
Worcester, MA

Steven R. DeMeester, MD

Thoracic, Foregut and Minimally Invasive Surgery
The Oregon Clinic
Portland, Oregon

Demetrios Demetriades, MD, PhD

Professor of Surgery
Director of Trauma, Emergency Surgery, Surgical Critical Care
University of Southern California
Los Angeles, California

Justin B. Dimick, MD, MPH

George D. Zuidema Professor of Surgery
Director, Center for Healthcare Outcomes & Policy
Chief, Division of Minimally Invasive Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Gerard M. Doherty, MD

Surgeon-in-Chief
Brigham and Women's Health Care & Dana-Farber Cancer Institute
Moseley Professor of Surgery
Harvard Medical School
Boston, Massachusetts

Christine Durand, MD

Assistant Professor of Medicine and Oncology Division of Infectious Diseases
The Johns Hopkins University School of Medicine
Baltimore, Maryland

Jean C. Emond, MD

Thomas S. Zimmer Professor of Surgery
Director of Transplantation
Columbia University and The New York Presbyterian Hospital
New York, New York

Michael J. Englesbe, MD

Associate Professor of Surgery
Division of Transplantation
University of Michigan
Ann Arbor, Michigan

Anthony L. Estrera, MD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Sandy H. Fang, MD

Assistant Professor
Department of Surgery
Ravitch Division, Colon and Rectal Surgery
Johns Hopkins Hospital
Baltimore, Maryland

Robert L. Ferris, MD, PhD

Professor
Vice-Chair for Clinical Operations
Chief, Division of Head and Neck Surgery
Associate Director for Translational Research
Co-Leader, Cancer Immunology Program
University of Pittsburgh Cancer Institute
Pittsburgh, Pennsylvania

Robert J. Fitzgibbons, Jr., MD

Harry E. Stuckenhoff Professor and Chairman
Department of Surgery
Creighton University School of Medicine
Medical Director of Surgical Services and Anesthesia

Alegent Creighton Clinic
Co-editor-in-Chief, Hernia
Omaha, Nebraska

James W. Fleshman, MD

Helen Buchanan and Stanley Joseph Seeger Professor and Chairman
Department of Surgery
Baylor University Medical Center
Professor of Surgery
Texas A&M Health Science Center
Dallas, Texas

Yuman Fong, MD

Professor and Chairman
Department of Surgery
City of Hope Medical Center
Duarte, California

Douglas L. Fraker, MD

Jonathan E. Rhoads Associate Professor of Surgery
Chief, Division of Surgical Oncology
University of Pennsylvania
Philadelphia, Pennsylvania

Heidi Frankel, MD

Department of Surgery
University of Southern California
Los Angeles, California

Chris E. Freise, MD

Professor of Surgery
Transplant Division
University of California
San Francisco, California

Samir K. Gadepalli, MD

Clinical Lecturer
Co-Director of Pediatric Surgical Critical Care
University of Michigan
Ann Arbor, Michigan

Julio Garcia-Aguilar, MD, PhD

Chief, Colorectal Service
Benno C. Schmidt Chair in Surgical Oncology
Memorial Sloan Kettering Cancer Center
New York, New York

Paul G. Gauger, MD

William J. Fry Professor of Surgery
Professor of Learning Health Sciences
Program Director – General Surgery
Division Head – Endocrine Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Ravi K. Ghanta, MD

Assistant Professor of Surgery
Division of Cardiothoracic Surgery

University of Virginia
Charlottesville, Virginia

Kristina A. Giles, MD

Assistant Professor of Surgery
Division of Vascular Surgery and Endovascular Therapy
University of Florida College of Medicine
Gainesville, Florida

William E. Gillanders, MD

Professor of Surgery
Washington University School of Medicine
Attending Surgeon
Barnes-Jewish Hospital
St. Louis, Missouri

A. Marc Gillinov, MD

Staff Surgeon
The Judith Dion Pyle Chair in Heart Valve Research
Department of Thoracic and Cardiovascular Surgery
Cleveland Clinic
Cleveland, Ohio

Jason S. Gold, MD

Department of Surgery
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts
Chief of Surgical Oncology
Surgical Service
VA Boston Healthcare System
West Roxbury, Massachusetts

Batya R. Goldwasser, DMD, MD

Oral and Maxillofacial Surgeon
Former Fellow and Resident
Department of Oral and Maxillofacial Surgery
Massachusetts General Hospital
Boston, Massachusetts

Niraj J. Gusani, MD, MS

Associate Professor of Surgery, Medicine, & Public Health Sciences
Section of Surgical Oncology
Penn State College of Medicine
Director, Program for Liver, Pancreas, & Foregut Tumors
Co-Medical Director, Outpatient Services
Penn State Cancer Institute
Hershey, Pennsylvania

Jonathan W. Haft, MD

Associate Professor, Cardiac Surgery
University of Michigan
Ann Arbor, Michigan

Mark R. Hemmila, MD

Professor of Surgery
Division of Acute Care Surgery
University of Michigan
Ann Arbor, Michigan

Peter K. Henke, MD

Leland Ira Doan Professor of Surgery
Chief, Vascular Surgery AAVA
University of Michigan
Ann Arbor, Michigan

Jennifer C. Hirsch-Romano, MD

Assistant Professor of Cardiac Surgery & Pediatrics
Associate Director, Pediatric Cardiothoracic Intensive Care Unit
C.S. Mott Children's Hospital
Ann Arbor, Michigan

John B. Holcomb, MD

Professor of Surgery
University of Texas Health Science Center
Houston, Texas

Michael G. House, MD

Associate Professor of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Thomas S. Huber, MD, PhD

Professor of Surgery
Chief, Division of Vascular Surgery and Endovascular Therapy
University of Florida College of Medicine
Gainesville, Florida

David T. Hughes, MD

Assistant Professor of Surgery
Department of Surgery
Division of Endocrine Surgery
University of Michigan
Ann Arbor, Michigan

Kenji Inaba, MD

Associate Professor of Surgery, Emergency Medicine, and Anesthesia
Division of Trauma and Surgical Critical Care
University of Southern California
Los Angeles, California

Craig M. Jarrett, MD, MBA

Fellow in Cardiothoracic Surgery
Division of Cardiac Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Eric K. Johnson, MD

MultiCare Colon and Rectal Surgery
Tacoma, Washington
Associate Professor of Surgery
Uniformed Services University of the Health Sciences
Bethesda, Maryland

Timothy M. Johnson, MD

Lewis and Lillian Becker Professor
Department of Dermatology
University of Michigan
Ann Arbor, Michigan

Bellal Joseph, MD,
Associate Professor of Surgery
University of Arizona
Tucson, Arizona

Gregory J. Jurkovich, MD
Professor and Vice-Chairman
Department of Surgery
UC Davis Health System
Sacramento, California

Leonard B. Kaban, MD, DMD
Chief, Oral and Maxillofacial Surgery
Massachusetts General Hospital
Boston, Massachusetts

Loay S. Kabbani, MD
Senior Staff Surgeon
Department of Vascular Surgery
Henry Ford Hospital
Detroit, Michigan

Jussuf T. Kaifi, MD, PhD
Assistant Professor of Surgery
Chief, Thoracic Surgery
Department of Surgery
University of Missouri
Columbia, Missouri

Giorgos C. Karakousis, MD
Assistant Professor of Surgery
Division of Endocrine and Oncologic Surgery
University of Pennsylvania
Philadelphia, Pennsylvania

George Kasotakis, MD, MPH
Assistant Professor of Surgery
Boston University Medical School
Division of Trauma, Acute Care Surgery & Surgical Critical Care
Department of Surgery
Boston Medical Center
Boston, Massachusetts

Kaitlyn J. Kelly, MD
Assistant Professor of Surgery
Division of Surgical Oncology
Moores Cancer Center
University of California, San Diego
La Jolla, California

Sachin Kheterpal, MD
Associate Professor of Anesthesiology
University of Michigan
Ann Arbor, Michigan

Eric T. Kimchi, MD, MBA
Associate Professor of Surgery
Chief, Surgical Oncology
Medical Director, Ellis Fischel Cancer Center

University of Missouri
Columbia, Missouri

Martyn Knowles, MD

Assistant Professor
Division of Vascular and Endovascular Surgery
University of Texas Southwestern
Dallas, Texas

David A. Kooby, MD

Professor of Surgery
Director of Surgical Oncology
Emory/Saint Joseph's Hospital
Director of Minimally Invasive GI Surgical Oncology
Emory University School of Medicine
Winship Cancer Institute
Atlanta, Georgia

Marijan Koprivanac, MD, MS

Resident
Department of General Surgery Research Fellow
Department of Cardiothoracic Surgery
Cleveland Clinic
Clinical Instructor
Case Western University
Cleveland, Ohio

Lauren A. Kosinski, MD

Welkin Group, Inc.
Chestertown, Maryland

Jeffrey H. Kozlow, MD, MS

Clinical Assistant Professor
Section of plastic Surgery
University of Michigan
Ann Arbor, Michigan

Devi Mukkai Krishnamurty, MD

Clinical Fellow
Colon and Rectal Surgery
Washington University School of Medicine-Barnes Jewish Hospital
St. Louis, Missouri

William M. Kuzon, Jr., MD, PhD

Reed O. Dingman Professor of Surgery
Section of Plastic Surgery
University of Michigan
Chief of Surgery
Ann Arbor VA Healthcare
Ann Arbor, Michigan

David W. Larson, MD, MBA

Professor of Surgery and Chair
Division of Colon and Rectal Surgery
Mayo Clinic
Rochester, Minnesota

Adriana Laser, MD

University of Maryland Medical Center

Baltimore, Maryland

Harish Lavu, MD

Section Chief HPB Surgery
Associate Professor
Thomas Jefferson University
Philadelphia, Pennsylvania

Steven G. Leeds, MD

Assistant Clinical Professor of Surgery
Texas A&M College of Medicine
Medical Director of MIS Research and Surgical Simulation
Division of Minimally Invasive Surgery
Baylor University Medical Center at Dallas
Dallas, Texas

Benjamin Levi, MD

Director, Burn/Wound and Regenerative Medicine Laboratory
Director, Burn Reconstruction and Scar Rehabilitation Program
Assistant Professor in Surgery
Divisions of Plastic and Reconstructive Surgery and Burn Surgery
University of Michigan
Ann Arbor, Michigan

Edward A. Levine, MD

Professor of Surgery
Chief, Surgical Oncology
Wake Forest University
Winston-Salem, North Carolina

Keith D. Lillemoe, MD

W. Gerald Austen Professor of Surgery, Harvard Medical School
Chief of Surgery and Surgeon-in-Chief
The Massachusetts General Hospital
Boston, Massachusetts

Jules Lin, MD

Surgical Director, Lung Transplant
Associate Professor
Section of Thoracic Surgery
University of Michigan
Ann Arbor, Michigan

Kirk Ludwig, MD

The Vernon O. Underwood Professor
Professor of Surgery
Chief, Division of Colorectal Surgery
Department of Surgery
Medical College of Wisconsin
Milwaukee, Wisconsin

Felix Y. Lui, MD

Associate Professor of Surgery
Section of General Surgery, Trauma, and Surgical Critical Care
Yale School of Medicine
New Haven, Connecticut

James D. Luketich, MD

Chairman, Department of Cardiothoracic Surgery

University of Pittsburgh Medical Center
University of Pittsburgh
Henry T. Bahson Professor of Cardiothoracic Surgery
Chairman, Department of Cardiothoracic Surgery
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Geoffrey T. Manley, MD, PhD

Professor and Vice Chairman of Neurological Surgery
University of California, San Francisco
Chief of Neurosurgery, San Francisco General Hospital
Co-Director, Brain and Spinal Injury Center
San Francisco, California

John C. Mansour, MD

Surgical Oncologist
Associate Professor Surgery
Chief, Division of Surgical Oncology
Department of Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

David J. Maron, MD, MBA

Vice Chair
Department of Colorectal Surgery
Cleveland Clinic Florida
Weston, Florida

Juan L. Martinez-Poyer, MD

Clinical Assistant Professor of Obstetrics and Gynecology
Perelman School of Medicine
University of Pennsylvania
Attending Physician, The Center for Fetal Diagnosis and Treatment
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Michael R. Marvin, MD

Chief, Division of Transplantation
Director of Liver Transplantation
Associate Professor of Surgery
University of Louisville
Jewish Hospital
Louisville, Kentucky

Peter T. Masiakos, MS, MD

Associate Professor of Surgery, Harvard Medical School
Associate Visiting Pediatric Surgeon
Director, Pediatric Trauma Service
Massachusetts General Hospital
Boston, Massachusetts

Michael R. Mathis, MD

Clinical Lecturer, Anesthesiology
University of Michigan
Ann Arbor, Michigan

Amit K. Mathur, MD, MS

Assistant Professor of Surgery
Mayo Medical School

Senior Associate Consultant
Transplant Surgery
Mayo Clinic Arizona
Phoenix, Arizona

Tomislav Mihaljevic, MD

Professor of Surgery
Cleveland Clinic Lerner College of Medicine
Chief Executive Officer, Cleveland Clinic Abu Dhabi
Abu Dhabi, UAE

Dianna Milewicz, MD, PhD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Michael J. Miller, MD

Chairman
Department of Plastic Surgery
The Ohio State University Wexner Medical Center
Columbus, Ohio

Charles C. Miller III, PhD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute
Houston, Texas

Rebecca M. Minter, MD

Professor of Surgery
Alvin Baldwin, Jr. Chair in Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Jason S. Mizell, MD

Assistant Professor of Surgery
Division of Colon and Rectal Surgery
Director of Surgery Clerkship
University of Arkansas for Medical Sciences
Little Rock, Arkansas

J. Gregory Modrall, MD

Professor of Surgery
Division of Vascular and Endovascular Surgery
University of Texas Southwestern Medical Center
Dallas, Texas

Adeyiza O. Momoh, MD

Assistant Professor of Surgery
Section of Plastic Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Gregory L. Moneta, MD

Professor of Surgery, Chief of Vascular Surgery
Knight Cardiovascular Institute
Oregon Health & Science University

Portland, Oregon

Katherine A. Morgan, MD

Professor of Surgery
Division of Gastrointestinal and Laparoscopic Surgery
Medical University of South Carolina
Charleston, South Carolina

Nathan Mowery, MD

Associate Professor of Surgery
Wake Forest University
Winston-Salem, North Carolina

Marc de Moya, MD

Associate Professor of Surgery
Acute Care Surgery Program Director
Division of Trauma, Acute Care Surgery
Department of Surgery
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Michael W. Mulholland, MD, PhD

Frederick A. Collier Distinguished Professor of Surgery
Chair, Department of Surgery
University of Michigan
Ann Arbor, Michigan

George B. Mychaliska, MD

Robert Bartlett, M.D. Collegiate Professor of Pediatric Surgery
Associate Professor of Surgery and Obstetrics and Gynecology
Director, Fetal Diagnosis and Treatment Center
Associate Chair for Faculty Development
Co-Director, ECMO Program
University of Michigan Medical School
Section of Pediatric Surgery
Department of Surgery
Ann Arbor, Michigan

Satish N. Nadig, MD, PhD

Assistant Professor Surgery, Microbiology, & Immunology
Transplant Surgery
Medical University of South Carolina
Charleston, South Carolina

Jeffry Nahmias, MD

Assistant Professor, Surgery
Tufts University School of Medicine
Director of Trauma Summer Undergraduate Research Program (T-SURP)
Baystate Medical Center
Springfield, Massachusetts

Attila Nakeeb, MD

Professor of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

Lena M. Napolitano, MD

Professor of Surgery

Division Chief, Acute Care Surgery
Director, Trauma and Surgical Critical Care
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Hari Nathan, MD, PhD

Assistant Professor
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Laura L. Neff, MD

Attending Otolaryngologist
Pediatric Otolaryngology
The Children's Mercy Hospital
Kansas City, Missouri

Erika Adams Newman, MD

Assistant Professor in Pediatric Surgery
Associate Program Director, General Surgery
Surgical Director, Mott Solid Tumor Oncology Program (MSTOP)
Translational Oncology Program
CS Mott Children's Hospital
The University of Michigan
Ann Arbor, Michigan

Trevor L. Nydam, MD

Assistant Professor and Transplant Surgeon
University of Colorado Hospital (UCH)
Aurora, Colorado

Robert W. O'Rourke, MD

Associate Professor
Department of Surgery
University of Michigan and Ann Arbor Veteran's Administration Hospital
Ann Arbor, Michigan

Daniel S. Oh, MD

Assistant Professor of Surgery
Division of Thoracic Surgery
Keck School of Medicine
University of Southern California
Los Angeles, California

Richard G. Ohye, MD

Professor of Cardiac Surgery
Head, Section of Pediatric Cardiovascular Surgery
Surgical Director, Pediatric Cardiovascular Transplant Program
Program Director, Congenital Cardiac Surgery Residency
Co-Director, Michigan Congenital Heart Center
Ann Arbor, Michigan

John A. Olson, Jr., MD, PhD

Campbell and Jeanette Plugge Professor of Surgery
Vice Chair, Department of Surgery
Chief, Division of General and Oncologic Surgery
The University of Maryland School of Medicine
Baltimore, Maryland

Mary F. Otterson, MD, MS

Professor of Surgery and Physiology
Medical College of Wisconsin
Zablocki Veteran Affairs Medical Center
Milwaukee, Wisconsin

Francis D. Pagani, MD, PhD

Otto Gago, MD Professor in Cardiac Surgery
Department of Cardiac Surgery
University of Michigan
Ann Arbor, Michigan

John M. Park, MD

Cheng-Yang Chang Professor of Pediatric Urology
Department of Urology
University of Michigan
Ann Arbor, Michigan

Pauline Park, MD

Department of Surgery
University of Michigan
Ann Arbor, Michigan

Richard N. Pierson III, MD

Professor of Surgery
Cardiac Surgery
University of Maryland School of Medicine
College Park, Maryland

Thomas H. Quinn, MS, PhD

Professor of Anatomy and Surgery
Assistant Dean for Medical Admissions
Past President, American Association of Clinical Anatomists
Creighton University School of Medicine
Omaha, Nebraska

Reza Rahbar, DMD, MD

Associate Otolaryngologist-in-Chief
McGill Chair in Pediatric Otolaryngology
Department of Otolaryngology
Boston Children's Hospital/Harvard Medical School
Boston, Massachusetts

Steven E. Raper, MD, JD

Associate Professor of Surgery
Department of Surgery
Perelman School of Medicine, University of Pennsylvania
Philadelphia, Pennsylvania

Todd E. Rasmussen, MD

Harris B Shumacker Professor of Surgery
The Uniformed Services University of the Health Sciences
Bethesda, Maryland

John E. Rectenwald, MD, MS

Associate Professor of Surgery & Radiology
Program Director, Vascular Surgery
Section of Vascular Surgery
University of Michigan

Ann Arbor, Michigan

Rishindra M. Reddy, MD

Assistant Professor of Thoracic Surgery
University of Michigan
Ann Arbor, Michigan

Amy B. Reed, MD

Chief and Program Director, Vascular Surgery
Heart and Vascular Institute
Penn State Hershey Medical Center
Hershey, Pennsylvania

Peter Rhee, MD, MPH

Senior Vice President
Chief of Acute Care Surgery and Trauma Medical Director
Grady Memorial Hospital
Atlanta, Georgia

Taylor S. Riall, MD, PhD

Professor, Chief of General Surgery and Surgical Oncology
Banner-University Medical Center
University of Arizona
Tucson, Arizona

Haris Riaz, MD

Resident physician
Department of Internal Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

William P. Robinson III, MD

Associate Professor
Division of Vascular and Endovascular Surgery
University of Virginia
Charlottesville, Virginia

Heron E. Rodriguez, MD

Associate Professor of Vascular Surgery
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Matthew R. Rosengart, MD, MPH

Associate Professor of Surgery, Critical Care Medicine
Director, University of Pittsburgh Surgical Critical Care Fellowship Program
Co-Director, University of Pittsburgh Department of Surgery, Surgical Outcomes Research Center
University of Pittsburgh
Pittsburgh, Pennsylvania

Michael S. Sabel, MD

Chief, Division of Surgical Oncology
Associate Professor of Surgery
University of Michigan Health System
Ann Arbor, Michigan

Hazim J. Safi, MD

Department of Cardiothoracic and Vascular Surgery
University of Texas Medical School at Houston
Memorial Hermann Heart & Vascular Institute

Houston, Texas

Ali Salim, MD

Professor
Harvard Medical School
Division Chief, Trauma, Burns, and Surgical Critical Care
Brigham and Women's Hospital
Boston, Massachusetts

Gordan Samoukovic, MD

Department of Cardiothoracic Surgery
McGill University
Montreal, Quebec
Canada

Gurjit Sandhu, PhD

Assistant Professor
Departments of Surgery and Learning Health Sciences
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Ariel P. Santos, MD, MPH

Assistant Professor
Associate Program Director of Emergency General Surgery
Department of Surgery
Division of Trauma, Acute Care and Critical Care Surgery
Penn State Milton S. Hershey Medical Center
Hershey, Pennsylvania

Mary C. Santos, MD

Associate Professor of Surgery and Pediatrics
Penn State College of Medicine
Penn State Children's Hospital
State College, Pennsylvania

Thomas T. Sato, MD

Professor of Surgery
Division of Pediatric Surgery
CEO, Children's Specialty Group
Senior Associate Dean of Clinical Affairs
Children's Hospital of Wisconsin and The Medical College of Wisconsin
Milwaukee, Wisconsin

Thomas M. Scalea, MD

Physician-in-Chief, Shock Trauma Center
System Chief for Critical Care Services
University of Maryland Medical System
The Honorable Francis X. Kelly Distinguished Professor in Trauma
Director, Program in Trauma
University of Maryland School of Medicine
Baltimore, Maryland

Richard D. Schulick, MD, MBA

The Aragón/Gonzalez-Gíustí Chair
Professor and Chair
Department of Surgery
University of Colorado Anschutz Medical Campus
Aurora, Colorado

Alexander D. Shepard, MD

Head, Division of Vascular Surgery
Szilagyi Chair in Vascular Surgery
Henry Ford Hospital
Professor of Surgery
Wayne State University School of Medicine
Detroit, Michigan

Junichi Shindoh, MD, PhD

Assistant Professor
Hepatobiliary-pancreatic Surgery Division
Department of Surgery
Graduate School of Medicine
The University of Tokyo
Tokyo, Japan

Matthew J. Sideman, MD

Associate Professor
Department of Surgery
Vascular Surgery Division
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Raymond Malcolm Smith, MB CHB, MD

Chief, Orthopaedic Trauma Service
Massachusetts General Hospital
Associate Professor of Orthopaedics
Harvard Medical School
Boston, Massachusetts

Elizabeth S. Soukup, MD, MMSc

Pediatric Surgeon, Elliot Health System
Assistant Professor of Surgery
Geisel School of Medicine
Dartmouth Hitchcock Medical Center
Hanover, New Hampshire

David I. Soybel, MD

David L. Nahrwold Professor of Surgery
Division Chief, General Surgery Specialties & Surgical Oncology
Penn State Hershey Medical Center
Hershey, Pennsylvania

Kevin F. Staveley-O'Carroll, MD, PhD

Hugh E. Stephenson, Jr., MD, Chair of Surgery
Director, Ellis Fischel Cancer Center
Professor of Surgery
University of Missouri
Columbia, Missouri

Scott R. Steele, MD

Vice Chairman for Clinical Affairs, Department of Surgery
Chief, Division of Colorectal Surgery
University Hospitals Case Medical Center
Professor of Surgery
Case Western Reserve University
Cleveland, Ohio

Peter G. Stock, MD, PhD

Professor of Surgery
University of California, San Francisco
San Francisco, California

Randall S. Sung, MD

Assistant Professor of Surgery
Surgical Director, Kidney and Pancreas Transplantation
University of Michigan
Ann Arbor, Michigan

Brooke Swearingen, MD

Professor of Neurosurgery
Neurosurgical Service, Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Phiroz E. Tarapore, MD

Assistant Professor of Clinical Neurosurgery
Department of Neurological Surgery
University of California San Francisco
San Francisco, California

Kevin E. Taubman, MD

Assistant Professor of Surgery and Program Director Vascular Surgery Fellowship
Section of Vascular and Endovascular Surgery
Department of Surgery
University of Oklahoma College of Medicine, Tulsa
Tulsa, Oklahoma

John R. Taylor III, MD

Clinical Instructor in Surgery
University of Texas Health Science Center
Houston, Texas

Carlos H. Timaran, MD

Chief, Endovascular Surgery
G. Patrick Clagett Professorship in Surgery
Associate Professor, Division of Vascular and Endovascular Surgery
University of Texas Southwestern
Dallas, Texas

Shahab Toursavadkahi, MD

Assistant Professor of Surgery
Division of Vascular Surgery
University of Maryland Medical Center
Baltimore, Maryland

Nicholas A. Tritos, MD, DSc

Neuroendocrine Unit
Department of Medicine
Massachusetts General Hospital
Assistant Professor of Medicine
Harvard Medical School
Boston, Massachusetts

Maria J. Troulis, DDS, MSc

Chief, Oral Maxillofacial Surgery
Massachusetts General Hospital

The University of Texas MD Anderson Cancer Center
Houston, Texas

George Velmahos, MD, PhD, MEd

John F. Burke Professor of Surgery
Harvard Medical School
Chief, Division of Trauma, Emergency Surgery, and Surgical Critical Care
Massachusetts General Hospital
Boston, Massachusetts

Christian J. Vercler, MD, MA

Assistant Professor
Section of Plastic Surgery
Department of Surgery
University of Michigan
Ann Arbor, Michigan

Richard B. Wait, MD, PhD

Professor Emeritus of Surgery
Tufts University School of Medicine
Boston, Massachusetts
Chairman of Surgery (retired)
Baystate Medical Center
Springfield, Massachusetts

Thomas W. Wakefield, MD

Stanley Professor of Vascular Surgery
Section Head, Section of Vascular Surgery, Department of Surgery
Director, Samuel and Jean Frankel Cardiovascular Center
University of Michigan
Ann Arbor, Michigan

J. Patrick Walker, MD

Chief of Surgery
Houston County Medical Center
Crockett, Texas
Vice-Chair of Education
Department of Surgery
University of Texas Medical Branch
Galveston, Texas

Julian Wan, MD

Reed Nesbit Professor of Urology
Department of Urology
University of Michigan
Ann Arbor, Michigan

Stewart C. Wang, MD, PhD

First Endowed Professor of Burn Surgery
Director, Burn Center
Director, State of Michigan Burn Coordinating Center
Director, Morphomic Analysis Group
Director, International Center for Automotive Medicine
University of Michigan
Ann Arbor, Michigan

Mitchell R. Weaver, MD

Assistant Clinical Professor
Division of Vascular Surgery
Henry Ford Hospital
Wayne State University School of Medicine
Detroit, Michigan

Sharon Weber, MD

Tim and MaryAnn McKenzie Chair of Surgery
Director for Surgical Oncology, UW Carbone Cancer Center
Vice Chair of Academic Affairs, General Surgery
Professor of Surgery, Department of Surgery
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Theodore H. Welling, MD

Assistant Professor of Surgery
Co-Director, Multidisciplinary Liver Tumor Program
Section of Transplantation
University of Michigan
Ann Arbor, Michigan

Hunter Wessells, MD

Professor and Nelson Chair
Department of Urology
University of Washington
Seattle, Washington

Steven D. Wexner, MD, PHD (Hon)

Director, Digestive Disease Center
Chair, Department of Colorectal Surgery
Cleveland Clinic Florida
Affiliate Professor, Florida Atlantic University College of Medicine
Clinical Professor, Florida International University College of Medicine
Miami, Florida

Edward E. Whang, MD

Department of Surgery
Brigham and Women's Hospital
Boston, Massachusetts

Elizabeth C. Wick, MD

Associate Professor of Surgery
University of California San Francisco
San Francisco, California

Edwin G. Wilkins, MD, MS

Professor of Surgery
Section of Plastic Surgery
University of Michigan
Ann Arbor, Michigan

Joshua H. Winer, MD

Assistant Professor of Surgery
Division of Surgical Oncology
Emory University/Saint Joseph's Hospital
Winship Cancer Institute
Atlanta VA Medical Center
Atlanta, Georgia

Sandra L. Wong, MD, MS

Professor and Chair
Department of Surgery
Dartmouth-Hitchcock Medical Center
Geisel School of Medicine at Dartmouth
Hanover, New Hampshire

Charles J. Yeo, MD

Samuel D. Gross Professor and Chairman
Department of Surgery
Jefferson Medical College
Thomas Jefferson University
Philadelphia, Pennsylvania

Adam C. Yopp, MD

Assistant Professor of Surgery
Department of Surgery
Division of Surgical Oncology
University of Texas Southwestern Medical Center
Dallas, Texas

Preface

The editors are pleased to present the sixth edition of *Greenfield's Surgery: Scientific Principles & Practice*. The field of surgery has changed fundamentally in the years since the first edition of this text. Growth in the knowledge base of clinical surgery continues exponentially. Surgical practice has been transformed through advancements in physiologic and cellular investigation, integration of new techniques derived from imaging and robotics, from the concept of patient-centered care, and from the emerging field of biocomputation. The accelerating pace of scientific progress demands rapid adoption of new ideas into surgical therapy and a commitment to lifelong learning. Accordingly, the new edition of *Greenfield's Surgery* seeks to integrate new scientific knowledge with evolving changes in surgical care.

The sixth edition has been enhanced in every way, with changes to the book's editorial board, authorship, content, organization, and visual presentation. It reflects the founding principles and guidance of Lazar J. Greenfield, MD, whose perceptive wisdom helped to create a truly unique book that balances scientific advance with clinical practice. With this new edition, we welcome new editors—Hasan Alam, MD and Timothy Pawlik, MD. Their expertise, energy, and vision have invigorated this edition.

We have solicited contributions from well over 200 authors, all chosen because of their scientific and clinical sophistication. Each contributor is currently an active practitioner in the field of surgery. Moreover, many have presented seminal articles and developed the new concepts in their disciplines that are featured in the text. Advances ranging from patient safety to fetal surgery mark the book as truly unique.

Organizationally, the book begins with topics of broad relevance to the practice of surgery, followed with chapters arranged by organ system. Trauma and transplantation are presented in the form of separate sections rather than subdivided chapters. The content within each has been presented as individual chapters in appreciation of the significance of each topic.

The book has been designed to create a text that not only looks better but also works better. The text is produced in a full range of colors, creating both visual impact and more opportunity to convey information quickly and with greater meaning. We continue our commitment to superb medical art in the form of line drawings. These illustrations have been enhanced to ensure a presentation that maximizes teaching effectiveness and clinical utility. Each chapter begins with a series of highlighted key teaching points, which are referenced within the text that follows. Individually numbered decision-making algorithms are featured throughout the book to provide diagnostic and management information in a simplified format. Tables carry classification bars, such as diagnosis or results, useful both when scanning the text for information and when accessing the book's contents digitally. The most important articles and chapters on the topic are highlighted in the reference list.

The sixth edition continues to be highly integrated with electronic elements to provide supplemental educational material, including Morbidity and Mortality Case Discussions and an interactive question bank.

Today, *Greenfield's Surgery: Scientific Principles & Practice* has become the gold standard text in the field of surgery. The editors continue their commitment to the education of contemporary surgeons, and to improved care of the patients that they serve. We believe that with the many improvements implemented in this sixth edition, it will continue to be the text by which all other surgery texts are judged.

Michael W. Mulholland, MD, PhD

Contents

Contributors

Preface

Part One Scientific Principles

1 Lifelong Learning

Gurjit Sandhu and Rebecca M. Minter

2 Principles of Intermediary Metabolism

Steven E. Raper

3 Surgical Nutrition and Metabolism

George Kasotakis

4 Obesity and Metabolic Disease

Robert W. O'Rourke and Michael W. Mulholland

5 Wound Healing

Rajiv Chandawarkar and Michael J. Miller

6 Hemostasis

Peter K. Henke and Thomas W. Wakefield

7 Inflammation

Matthew R. Rosengart and Timothy R. Billiar

8 Surgical Infections

Lena M. Napolitano

9 Shock

Joseph Cuschieri and Darren Bowe

10 Critical Care

Damon Clark and Heidi Frankel

11 Fluids, Electrolytes, and Acid–Base Balance

Richard B. Wait, M. George DeBusk, and Jeffry Nahmias

12 Burns

Benjamin Levi, Mark R. Hemmila, and Stewart C. Wang

13 Anesthesiology and Pain Management

Sachin Kheterpal and Michael R. Mathis

14 Oncology

Adam C. Yopp and John C. Mansour

15 Preoperative Risk Assessment

Pauline Park

16 Measuring the Quality of Surgical Care

Justin B. Dimick and John D. Birkmeyer

17 Policy Approaches to Improving Surgical Quality

John D. Birkmeyer and Justin B. Dimick

18 Patient Safety

Darrell A. Campbell, Jr.

Part Two Surgical Practice

SECTION A: TRAUMA

19 Trauma and Trauma Care: General Considerations

Hasan B. Alam

20 Prehospital and New Advances in Resuscitation

John R. Taylor III, John B. Holcomb, and Bryan A. Cotton

21 Head Trauma

Phiroz E. Tarapore, Geoffrey T. Manley, and Randall M. Chesnut

22 Maxillofacial Injuries

Batya R. Goldwaser, Leonard B. Kaban, and Maria J. Troulis

23 Neck Injuries

Brandon R. Bruns and Thomas M. Scalea

24 Thoracic Trauma

Marc de Moya and George Velmahos

25 Abdominal Trauma

Kenji Inaba, Elizabeth R. Benjamin, and Demetrios Demetriades

26 Genitourinary Trauma

Hunter Wessells

27 Vascular Trauma

Adriana Laser, Shahab Toursavadkahi, and Todd E. Rasmussen

28 The Principles of Orthopedic Surgery for Trauma

Raymond Malcolm Smith

29 Pediatric Trauma

Elizabeth S. Soukup and Peter T. Masiakos

30 Geriatric Trauma

Carlos V.R. Brown, Zara Cooper, and Ali Salim

31 Trauma in Pregnancy

Felix Y. Lui and Kimberly A. Davis

32 Postinjury Management

Bellal Joseph and Peter Rhee

33 Environmental Injuries

J. Patrick Walker and Gregory J. Jurkovich

SECTION B: TRANSPLANTATION

34 Clinical Transplant Immunology

Amit K. Mathur and Satish N. Nadig

35 Organ Procurement and Preservation

Michael J. Englesbe

36 Renal Transplantation

Chris E. Freise and Peter G. Stock

37 Hepatic Transplantation

Theodore H. Welling

38 Cardiac Transplantation

Richard N. Pierson III

39 Pulmonary Transplantation

Jules Lin and Andrew C. Chang

40 Pancreas and Islet Transplantation

Randall S. Sung

SECTION C: HEAD AND NECK

41 Head and Neck

J. Kenneth Byrd and Robert L. Ferris

SECTION D: ESOPHAGUS

42 Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease

Daniel S. Oh and Steven R. DeMeester

43 Esophageal Tumors and Injury

Jonathan D'Cunha and James D. Luketich

SECTION E: STOMACH AND DUODENUM

44 Gastric Anatomy and Physiology

Michael W. Mulholland

45 Gastroduodenal Ulceration

Michael W. Mulholland

46 Management of Obesity

Robert W. O'Rourke

47 Gastric Neoplasms

Hari Nathan and Rebecca M. Minter

SECTION F: SMALL INTESTINE

48 Anatomy and Physiology of the Small Intestine

E. Ramsay Camp, Kevin F. Staveley-O'Carroll, Niraj J. Gusani, Jussuf T. Kaifi, and Eric T. Kimchi

49 Ileus and Bowel Obstruction

David I. Soybel and Ariel P. Santos

50 Crohn Disease

Scott R. Steele and Eric K. Johnson

51 Small Bowel Tumors

Steven G. Leeds and James W. Fleshman

SECTION G: PANCREAS

52 Pancreas Anatomy and Physiology

Taylor S. Riall

53 Acute Pancreatitis

Jason S. Gold and Edward E. Whang

54 Chronic Pancreatitis

Katherine A. Morgan and David B. Adams

55 Neoplasms of Exocrine Pancreas

Attila Nakeeb, Michael G. House, and Keith D. Lillemoe

56 Neoplasms of the Endocrine Pancreas

Harish Lavu, Jonathan R. Brody, and Charles J. Yeo

SECTION H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM

57 Hepatobiliary Anatomy

Trevor L. Nydam and Richard D. Schulick

58 Hepatic Infection and Acute Liver Failure

Andrew M. Cameron and Christine Durand

59 Cirrhosis and Portal Hypertension

Michael R. Marvin, Robert M. Cannon, and Jean C. Emond

60 Hepatic Neoplasms

Junichi Shindoh and Jean-Nicolas Vauthey

61 Calculous Biliary Disease

David A. Kooby, Joshua H. Winer, and Kenneth Cardona

62 Biliary Injuries and Strictures and Sclerosing Cholangitis

Chad G. Ball and Keith D. Lillemoe

63 Biliary Neoplasms

Kaitlyn J. Kelly, Yuman Fong, and Sharon Weber

SECTION I: COLON AND RECTUM

64 Colon and Rectal Anatomy and Physiology

Sandy H. Fang and Elizabeth C. Wick

65 Acute Gastrointestinal Hemorrhage

Jason S. Mizell and Richard H. Turnage

66 Ulcerative Colitis

Dorin T. Colibaseanu and David W. Larson

67 Colonic Polyps and Polyposis Syndromes

Robert S. Bresalier and C. Richard Boland

68 Colorectal Cancer

Julio Garcia-Aguilar

69 Diverticular Disease

Lauren A. Kosinski, Kirk Ludwig, and Mary F. Otterson

70 Anorectal Disorders

David J. Maron and Steven D. Wexner

71 Diseases of Appendix

Edward A. Levine and Nathan Mowery

SECTION J: HERNIA AND SPLEEN

72 Abdominal Wall Hernias

Robert J. Fitzgibbons, Jr., Thomas H. Quinn, and Devi Mukkai Krishnamurty

73 The Spleen

Giorgos C. Karakousis and Douglas L. Fraker

SECTION K: SURGICAL ENDOCRINOLOGY

74 Breast Disease

Thanh U. Barbie and William E. Gillanders

75 Thyroid Gland

David T. Hughes and Paul G. Gauger

76 Parathyroid Glands

Gerard M. Doherty

77 Adrenal Gland

John A. Olson, Jr. and Douglas J. Turner

78 Pituitary Surgery

Brooke Swearingen and Nicholas A. Tritos

SECTION L: LUNG

79 Lung Neoplasms

Andrew C. Chang and Jules Lin

80 Non-Neoplastic Thoracic Disease

Rishindra M. Reddy

SECTION M: VASCULAR DISEASE

81 Congenital Heart Disease

Jennifer C. Hirsch-Romano, Richard G. Ohye, and Edward L. Bove

82 Valvular Heart Disease and Cardiac Tumors

Tomislav Mihaljevic, Craig M. Jarrett, Husain T. AlQattan, Shehab Ahmad Redha AlAnsari, Haris Riaz, Marijan Koprivanac, and A. Marc Gillinov

83 Ischemic Heart Disease

Jonathan W. Haft

84 Mechanical Circulatory Support for Cardiac Failure

Gordan Samoukovic and Francis D. Pagani

85 Thoracic Aortic Aneurysms and Aortic Dissection

Ravi K. Ghanta and Gorav Ailawadi

86 Pericardium

Jules Lin

87 Vascular Diagnostics: The Noninvasive Vascular Laboratory

Gregory L. Moneta

88 Vascular Infection

Jayer Chung and J. Gregory Modrall

89 Cerebrovascular Disease

Martyn Knowles and Carlos H. Timaran

90 Upper Extremity Arterial Disease

Heron E. Rodriguez

91 Renal and Splanchnic Vascular Disease

Dawn M. Coleman, John E. Rectenwald, and Gilbert R. Upchurch, Jr.

92 Aortoiliac Disease

Loay S. Kabbani, Mitchell R. Weaver, and Alexander D. Shepard

93 Peripheral Arterial Disease

William P. Robinson III

94 Lower Extremity Amputation

Matthew J. Sideman, Kevin E. Taubman, and Bradley D. Beasley

95 Thoracoabdominal Aortic Aneurysms

Hazim J. Safi, Anthony L. Estrera, Charles C. Miller III, Kristofer M. Charlton-Ouw, Dianna Milewicz, and Ali Azizzadeh

96 Abdominal Aortic Aneurysms

Adam W. Beck, Kristina A. Giles, and Thomas S. Huber

97 Lower Extremity Aneurysms

Amy B. Reed

98 Venous Disease

Thomas W. Wakefield and Michael C. Dalsing

SECTION N: PEDIATRIC SURGERY

99 Fetal, Neonatal, and Pediatric Physiology

Samir K. Gadepalli and George B. Mychaliska

100 Fetal Intervention

George B. Mychaliska and Darrell L. Cass

101 Pediatric Head and Neck

Laura L. Neff and Reza Rahbar

102 The Pediatric Chest

Mary C. Santos and Robert E. Cilley

103 Pediatric Abdomen

Thomas T. Sato and Marjorie J. Arca

104 Pediatric Genitourinary System

John M. Park and Julian Wan

105 Childhood Tumors

Erika Adams Newman

106 The Pregnant Patient

Juan L. Martinez-Poyer and N. Scott Adzick

SECTION O: SKIN AND SOFT TISSUE

107 Cutaneous Neoplasms

Michael S. Sabel, Timothy M. Johnson, and Christopher K. Bichakjian

108 Sarcomas of Soft Tissue and Bone

Sandra L. Wong

109 Plastic and Reconstructive Surgery

Christian J. Vercler, David L. Brown, Steven R. Buchman, Paul S. Cederna, Kevin C. Chung, Jeffrey H. Kozlow, William M. Kuzon, Jr., Adeyiza O. Momoh, and Edwin G. Wilkins

Index

List of Algorithms

Algorithm 8-1.	Empiric antimicrobial treatment of extrabiliary cIAs, community acquired versus healthcare associated
Algorithm 8-2.	Biliary infections and algorithm for diagnosis and management
Algorithm 8-3.	Step-up approach to management of necrotizing infected pancreatitis
Algorithm 9-1.	Neurohormonal response to hypovolemia
Algorithm 9-2.	Shock resuscitation algorithm
Algorithm 11-1.	Hyponatremia
Algorithm 11-2.	Acute hyperkalemia
Algorithm 11-3.	Guidelines for the treatment of diabetic ketoacidosis
Algorithm 12-1.	Protocol for frostbite injury
Algorithm 13-1.	Decision aid for preoperative cardiac evaluation prior to noncardiac surgery. This decision tree for preoperative evaluation takes into account not only the patient's physical status but also the severity of the surgical procedure
Algorithm 13-2a-b.	Algorithm for managing a patient on chronic buprenorphine therapy
Algorithm 15-1.	Stepwise Approach to Perioperative Cardiac Assessment for CAD
Algorithm 15-2.	Proposed algorithm for antiplatelet management in patients with PCI and noncardiac surgery
Algorithm 15-3.	Preoperative evaluation of patients with lung cancer for resection
Algorithm 15-4.	Proposed algorithm for preoperative evaluation of patients with liver disease
Algorithm 19-1.	2011 Guidelines for the Field Triage of the Injured Patients
Algorithm 21-1.	Glasgow Coma Scale (GCS) triage guide for initial evaluation of head injury. For the motor scale, the best response for any limb is recorded
Algorithm 21-2.	Prehospital evaluation and treatment of a patient with severe traumatic brain injury. "Signs of increased ICP" is the decision point for determining the necessity of intracranial pressure (ICP)-lowering therapy. These signs include pupillary abnormalities, motor posturing, or neurologic deterioration not related to medications. The order of steps is determined by the risk–benefit ratio for individual treatment maneuvers. This algorithm should be viewed as "expert opinion" and used as a framework, which may be useful in guiding an approach to field management of such patients
Algorithm 21-3.	Evaluation and treatment of the patient with severe traumatic brain injury on arrival at the trauma center. The order of steps is determined by the risk–benefit ratio for individual treatment maneuvers. This algorithm should be viewed as "expert opinion" and used as a framework, which may be useful in guiding an approach to initial hospital management of such patients prior to the initiation of ICP monitoring
Algorithm 26-1.	Algorithm for the evaluation and management of renal injury
Algorithm 26-2.	Algorithm for the evaluation and management of ureteral injury
Algorithm 26-3.	Algorithm for the evaluation and management of urethral injury
Algorithm 28-1.	The Denver Protocol for management of major pelvic fractures
Algorithm 29-1.	PECARN rules to identify children at very low risk of clinically important TBI. CT algorithm for children younger than 2 years (A) and for those aged 2 years and older (B) with GCS scores of 14–15 after head trauma
Algorithm 29-2a-b.	Algorithm generated by the Brain Trauma Foundation Committee for the first edition of the <i>Guidelines for the Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents</i> for first-tier therapies (A) and second-tier therapies (B)
Algorithm 29-3.	New ATOMAC guidelines for management of pediatric solid organ injury
Algorithm 36-1.	Stepwise approach to the management of decreased low urine output posttransplant

Algorithm 39-1.	The donor management algorithm used at the University of Michigan in coordination with the organ procurement organization, Gift of Life. Optimal PEEP is determined by increasing PEEP 2 cm of H ₂ O every 3 to 5 minutes until compliance decreases. Recruitment maneuvers include CPAP at 30 cm of H ₂ O for 30 seconds every 20 minutes × 3
Algorithm 41-1.	Workup of a Neck Mass in an Adult Patient
Algorithm 42-1.	24-Hour Esophageal pH Monitoring
Algorithm 43-1.	Evaluation and treatment of esophageal perforation
Algorithm 43-2.	Proposed algorithm for evaluation and management of acute caustic ingestion
Algorithm 43-3.	Evaluation and treatment of esophageal leiomyoma
Algorithm 45-1.	Treatment of bleeding duodenal ulceration
Algorithm 46-1.	Algorithm for management of abdominal pain months or years after Roux-en-Y reconstruction
Algorithm 47-1.	Treatment of gastric adenocarcinoma
Algorithm 49-1.	Algorithm for the management of adhesive small bowel obstruction
Algorithm 49-2.	Approach to the management of malignant bowel obstruction
Algorithm 50-1.	Crohn disease with anal complaints
Algorithm 50-2.	Anal skin tags in Crohn disease
Algorithm 50-3.	Hemorrhoids in Crohn disease
Algorithm 50-4.	Anal abscess/fistula in Crohn disease
Algorithm 50-5.	Anal fissure in Crohn disease
Algorithm 50-6.	Anal stenosis/stricture and Crohn disease
Algorithm 51-1.	Management algorithm for patients with advanced neuroendocrine tumors (NETs) of the gastrointestinal tract
Algorithm 51-2.	Algorithm showing the management of patients with small bowel adenocarcinomas. The treatment strategy depends on disease stage and involves en bloc resection for locoregional disease and systemic chemotherapy for metastatic disease. All current recommendations are based on case series, retrospective reviews or nonrandomized prospective trials because of an absence of any randomized data
Algorithm 51-3.	Treatment algorithms for patients with (A) advanced/metastatic GIST and (B) resectable GIST. GIST indicates gastrointestinal stromal tumor
Algorithm 53-1.	Algorithm for the management of acute pancreatitis
Algorithm 54-1.	Algorithm for operative decision-making in chronic pancreatitis
Algorithm 55-1.	International consensus guidelines for the management of IPMNs
Algorithm 55-2.	Management strategy based on CT criteria for resectability of pancreatic cancer
Algorithm 56-1.	Diagnosis and management of pancreatic endocrine neoplasms
Algorithm 59-1.	Suggested treatment options, in order of preference, for patients who fail medical management for variceal bleeding
Algorithm 60-1.	BCLC algorithm for treatment selection in patients with HCC
Algorithm 60-2.	Treatment algorithm of patients with hepatocellular carcinoma (HCC) based on serum bilirubin level and indocyanine green retention rate at 15 minutes
Algorithm 60-3.	Multidisciplinary treatment approach for colorectal liver metastasis
Algorithm 61-1.	Algorithm for the management of common bile duct stones
Algorithm 61-2.	Management of acute cholangitis
Algorithm 62-1.	Algorithm for diagnosis and management of bile duct injury associated with laparoscopic cholecystectomy
Algorithm 65-1.	Diagnostic steps in the evaluation of gastrointestinal hemorrhage
Algorithm 68-1.	Approach to rectal cancer according to clinical staging
Algorithm 68-2.	Approach to locally advanced rectal cancer based on a three-tier risk stratification system (“the good, the bad, and the ugly”)
Algorithm 68-3.	Stage IV rectal cancer treatment algorithm
Algorithm 69-1.	Diverticulitis Treatment based on Modified Hinchey Score (0–IV)

Algorithm 72-1.	Management of initial inguinal hernia
Algorithm 72-2.	Management of recurrent inguinal hernia
Algorithm 72-3.	Management of groin pain after herniorraphy
Algorithm 72-4.	Management of incisional hernia
Algorithm 74-1.	Diagnosis and management of the patient with a clinically benign breast mass. The use of imaging studies varies according to age because breast carcinoma is infrequent in women younger than 35 years old
Algorithm 74-2.	Diagnosis and management of the patient with a clinically indeterminate or suspicious solid breast mass. In this circumstance, imaging studies are insufficient to exclude malignancy, and tissue sampling is required
Algorithm 74-3.	Diagnosis and management of the patient with a cystic lesion. Bloody fluid on aspiration, failure of the mass to resolve completely, and prompt refilling of the same cyst are indications for surgical biopsy
Algorithm 74-4.	Management of the patient with an abnormal screening mammogram. When pathology is benign, concordance or discordance with imaging findings dictates whether surgical excisional biopsy is indicated
Algorithm 75-1.	Management algorithm for thyroid mass
Algorithm 77-1.	Diagnosis of hypercortisolism
Algorithm 77-2.	Diagnosis and management of hyperaldosteronism
Algorithm 77-3.	Diagnosis and management of the incidental adrenal mass
Algorithm 78-1.	Treatment algorithm for acromegaly
Algorithm 78-2.	Treatment algorithm for Cushing disease
Algorithm 79-1.	Management of the incidental solitary pulmonary nodule
Algorithm 79-2.	Evaluation of the patient who presents with a pulmonary mass
Algorithm 79-3.	This algorithm illustrates the preoperative functional evaluation prior to lung cancer resection
Algorithm 80-1.	Algorithm for management of lung abscess
Algorithm 80-2.	Hemoptysis management
Algorithm 80-3.	LVRS candidate workup
Algorithm 80-4.	Algorithm to treat pneumothorax.
Algorithm 80-5.	Algorithm for management of tracheal masses
Algorithm 84-1.	Current algorithm for assessing patients with advanced heart failure for heart transplantation and mechanical circulatory support. Transplant status is initially assessed to determine appropriate indication for MCS use; BTT vs. DT
Algorithm 86-1.	This algorithm outlines the initial approach to a patient with a large pericardial effusion
Algorithm 92-1.	Patient with symptomatic aortoiliac occlusive disease
Algorithm 97-1.	Management of femoral pseudoaneurysm
Algorithm 98-1.	Treatment of chronic venous insufficiency

Part One **Scientific Principles**

Chapter 1

Lifelong Learning

Gurjit Sandhu and Rebecca M. Minter

Key Points

- 1 Self-regulated learning is a skill that can be taught to trainees.
 - 2 The Dreyfus model of skill development is helpful for understanding the growth and depth of self-regulated learning from novice to expert level.
 - 3 As self-regulated learning solidifies and becomes habitual for the trainee, it enhances transitions into effective lifelong learning.
 - 4 Lifelong learning is an essential component of safe patient care with up-to-date knowledge and skills.
 - 5 Surgeons who are lifelong learners are better prepared to deal with the complexities of future practice.
-

LIFELONG LEARNING FOR PERSONAL, PROFESSIONAL, AND SOCIAL RESPONSIBILITY

The Accreditation Council for Graduate Medical Education (ACGME) Task Force on Quality Care and Professionalism has drawn a clear and explicit connection among professionalism, safe patient care, and lifelong learning.¹ This is a direct reference to ensuring that graduate medical education programs are graduating fully trained physicians who are prepared to practice independently.^{1,2} In order to achieve this goal, *exposure* to the curriculum is insufficient. Surgeons in training must demonstrate that they are able to perform the activities of a specialist in that field. This becomes a complex feat of curriculum development and learner assessment when one considers that even as learners are graduating from their training programs, their specialties are evolving. With a patient population that is older, has higher acuity, greater number of chronic diseases and comorbidities, accompanied with unprecedented growth in medical knowledge, it is naive to assume that trainees will graduate with mastery of every facet of their discipline.^{3,4} Hence, graduating physicians who are primed for lifelong learning becomes a salient professional and social responsibility of graduate medical education programs.

Ultimately, lifelong learning is about bringing together individual responsibility with safe patient care. The commitment to ongoing reflective learning lends itself to a practice where research, education, and experience come together to best serve the needs of the patient. ACGME emphasis on lifelong learning is evidenced in two concrete ways: (1) by the continuum with which milestones are developed – beginning with the pretrained novice and extending throughout the physician’s career – reinforcing learning and growth beyond graduation; and (2) an explicit ACGME Common Program Requirement stating “residents must demonstrate the ability to investigate and evaluate their care of patients, to appraise and assimilate scientific evidence, and to continuously improve patient care based on constant self-evaluation and lifelong learning.”^{5,6} Several surgical specialties have gone on to include lifelong learning as a milestone within the practice-based learning and improvement competency.⁷⁻¹⁰

If lifelong learning is an outcome that is sought among high performing, safe, up-to-date surgeons, it is imperative that surgeons in training develop appropriate knowledge, skills, and attitudes during training that will foster this habitual behavior for when they are in professional practice. Just as management of complex problems or knowledge about postoperative complications of most essential operations are milestones that are met in a progressive manner, the same is true about lifelong learning as a milestone that is met in a progressive manner. As a trainee works toward honing and demonstrating expertise for lifelong learning, progressive development toward this goal while still in a residency program would be called self-regulated learning. In other words, the goal over time is for a resident/fellow to fully and intuitively adopt self-regulated learning and graduate from training entrusted to embrace lifelong learning. Before considering the development of self-regulated learning in

a graduated manner across the continuum of graduate medical education, it is important to define and establish the relationship between self-regulated and lifelong learning.

SELF-REGULATED LEARNING

1 Self-regulated learning has been used to describe students who are “metacognitively, motivationally, and behaviorally active participants in their own learning process.”¹¹ This includes the ability to plan and organize self-instruction, monitor and assess self, and seek out optimal learning opportunities. White et al.¹² argue that these are not merely innate attributes, but skills that can be taught during medical training. Self-regulated learning is framed as a cycle of four phases¹²:

1. Planning
2. Learning
3. Assessment
4. Adjustment

Planning is about setting personal goals, establishing desired outcomes, and having the belief in one’s ability to achieve those goals. In this phase, intrinsic motivation and extrinsic motivation are important considerations in the setting and reaching of learning goals. While extrinsic motivation is embedded in graduate medical education (e.g., passing certifying oral examinations), it is intrinsic motivation that is “key to the development of autonomy” and “autonomy is key to lifelong learning.”¹² Therefore, during the planning phase, learners develop a sense of urgency for their own learning and an ability to plan and act on goals.

During the *Learning* phase, learners need clarity about how they learn most effectively. This includes developing awareness about one’s personal beliefs toward acquiring knowledge, preferred ways of learning (e.g., visual, auditory), learning strategies (e.g., where and when studying happens), and finally aligning learning expectations with those of the educator.

Assessment requires timely, specific, and regular formative feedback (e.g., from supervisors, colleagues, medical students) as well as internal monitoring that compares one’s progress against the goal that was set. Together these sources of feedback guide the learner’s next steps toward reaching the goal.

Finally, *Adjustment* is where the learner synthesizes what has been gained through the planning, learning, and assessment phases and makes adjustments either in the nature of the goal or in the strategies needed to reach the goal. How learners integrate information about successes or failures could be seen as a matter of attribution – how performance is accounted for ranging from ability to effort. Examining the performance feedback that has been gathered to date, considering the validity of the information, and then determining how to make sense of it in relation to what they already know is a complex process of reflection.¹³

Through explicit teaching and practice at each phase, learners are guided toward sustaining strategies for ongoing, more effective self-regulated learning. Sustainable strategies form the basis for lifelong learning. White et al.¹² underscore sustainable strategies as a key to continuing medical education (CME) for the practicing surgeon and point to the link between CME and quality health care.

LIFELONG LEARNING

If the phases of self-regulated learning solidify for the trainee, they become **habitual** characteristics of effective lifelong learning. In the broadest sense, lifelong learning is about ongoing learning from cradle to grave. However, in the context of entering the workplace after graduate medical education, we look at physicians and lifelong learning more closely as the “ability to guide their own learning throughout their lives and in the wide variety of situations they will encounter after leaving formal education.”¹⁴

This ongoing reflexive process of lifelong learning includes five characteristics¹⁴:

1. set goals
2. apply appropriate knowledge and skills
3. engage in self-direction and self-evaluation
4. locate required information
5. adapt their learning strategies to different conditions

These characteristics are meant to extend the physician’s concept of ongoing learning from “lifelong schooling” to “life-wide learning” so that personal inquiry can happen, for example, at the bedside or in the community and is not constrained to formal educational opportunities.¹⁴

As a trainee transitions through different levels in residency, the nature of self-regulated learning will also change depending on the learner’s needs. As learners meet increasingly more complex patient care milestones, the practice of self-regulated learning transforms accordingly. Solidifying the phases of self-regulated learning during graduate medical education feeds into establishing effective characteristics for lifelong learning that become a critical part of a physician’s everyday practice (Table 1-1). As such, medical education programs have a social and professional obligation to further develop and deepen characteristics of self-regulated learning among learners so that graduating surgeons pursue professional learning throughout their careers.⁵ It is critically important that a robust curriculum be established within graduate medical education for teaching, engaging with, and assessing practices for lifelong learning.

Table 1-1 Relationship Between Self-Regulated Learning and Lifelong Learning

Self-Regulated Learning Phases	Lifelong Learning Characteristics
Planning	Set goals
Learning	Apply appropriate knowledge and skills
Assessment	Engage in self-direction and self-evaluation Locate required information
Adjustment	Adapt their learning strategies to different conditions

Self-regulated learning evolving and deepening into lifelong learning is best understood using the Dreyfus model for skill development.¹⁵ This is in keeping with the foundational framework from which the milestone frameworks have been structured to assess residents/fellows in surgical disciplines.¹

DREYFUS MODEL FOR SKILL DEVELOPMENT

The Dreyfus model for skill development identifies five levels of skill development¹⁵⁻¹⁷:

1. Novice
2. Advanced Beginner
3. Competent
4. Proficient
5. Expert

On this continuum, learners pass from one level to the next as skills are acquired. At each level, there are “recognizable, qualitatively different ways of acting and performing in the process of learning a given skill. Individuals at a given level do better than individuals at the previous level.”¹⁸ Table 1-2 presents the five levels of the Dreyfus model with the addition of delineating each level along four characteristics of skill development: knowledge; decision-making; perception of context; and autonomy.¹⁹⁻²³ Increasing understanding, confidence, and independence associated with these characteristics is in keeping with higher levels of competency with the skill being measured. This delineated view demonstrates in a granular way how a learner progresses and performs differently at each level. Based on criteria, it is clear why not every learner reaches the highest level. The criterion-based foundation of the Dreyfus model makes it a widely adapted process for assessment.^{23,24}

2 At the novice level, learners largely have textbook familiarity with a skill. After having advanced to the expert level, learners have extensive experiential knowledge with a skill and are seen to be highly intuitive. We understand self-regulated learning to be a skill that can be learned, will progressively grow and deepen over time, is carried out differently at each successive level, and ought to be carried out in the workplace. As the skill is honed and becomes habitual, self-regulated learning transitions into lifelong learning. This progression in skill development makes the Dreyfus model highly appropriate for understanding, teaching, and assessing self-regulated learning.

Table 1-2 Dreyfus Model of Skill Development: Novice to Expert Levels for Self-

Regulated Learning

Level	Characteristics			
	Knowledge	Decision-Making	Perception of Context	Autonomy
1. Novice	Primarily textbook knowledge with few previous experiences Context free following of taught rules Unconscious incompetence	Considers everything and makes tentative judgments with no flexibility Unable to deal with complexity when something unexpected happens Rational	Understand each action as a separate entity Analytic	Close supervision and instruction Observes procedure being performed
2. Advanced Beginner	Gaining practical experiences and knowledge Beginning to apply rules based on context Conscious incompetence	Perception improving, but judgments continue to be largely limited Realizes complexity of situation, but still has difficulty with troubleshooting Rational	Understands actions as related steps Analytic	Requires supervision for overall procedure Assists with performing a procedure and receives opportunities to try some tasks on own
3. Competent	Well-developed background of understanding, conceptual models, and working knowledge in a specialty Led by guidelines that are specific to each situation, yet sees the larger context Conscious competence	Handles complex situations through deliberate planning and own judgment Able to troubleshoot on own, but seeks out expert consult for confirmation Rational	Relates actions to long-term goals Analytic	Direct supervision Able to perform an entire procedure under direct supervision
4. Proficient	Depth of knowledge in field of practice Increasingly working from intuition with less dependence on rules; using analytic approaches primarily to address unusual problems in context Unconscious competence	Merges intuitive and analytic approaches in complex situations Uses pattern recognition to determine essential elements in a situation and what is a deviation Rational	Considers context holistically and how individuals contribute to it Holistic	With indirect supervision, takes full responsibility for performing a procedure Reflects on personal performance and experiences of others for continuous self-improvement
5. Expert	Influential authority in the field Intuitive understanding outweighs reliance on rules, yet uses analytic approaches in novel circumstances Deep understanding	Manages complex conditions with confident decision-making Uses pattern recognition in context and for forward planning Intuitive	Sees larger context and alternative approaches to what may be possible Holistic	Independently performs the procedure without any supervision Takes full responsibility for going beyond maxims

DREYFUS MODEL OF SKILL DEVELOPMENT APPLIED TO SELF-REGULATED LEARNING IN SURGERY

The attributes and practice of self-regulated learning change as learners transition from one level to the next. In other words, as learners attain greater levels of responsibility, the goals they set for themselves, insights adopted about learning, feedback they require, and adjustments they make based on successes and failures will be different from one level to the next. This is in line with gradually more mature forms of reflection and insightful learning plans learners develop for themselves. Self-regulated learning will be described at each level in terms of the learner's skills, but also includes suggestions for educators on how to teach at the level of the learner and establish scaffolds to support the learner advancing to the next level.^{23,24}

Novice

The novice learner is focused on figuring out how textbook knowledge applies to the current experience. The goals learners set for themselves are about making sense of uncertain or unfamiliar content by connecting it to existing familiar sets of knowledge. At this point, the learner adheres to step-by-step rules, regardless of context. Working through a methodical line of reasoning without situational awareness or discretion makes it difficult for the trainee to deal with exceptions and

complexity.²⁴ The learner searches for absolute answers. Tendencies toward binary sets of knowledge reveal that learners at this level often do not know what they do not know (unconscious incompetence), suggesting they have an incomplete development of self-assessment.²⁵ After routine-guided observations of procedures being performed, novice learners are incrementally moved to close supervision with explicit instruction in order to complete tasks. Reflecting on their behavior during experiential opportunities along with the feedback received from faculty or more senior residents and fellows causes learners to revisit the knowledge they believed to be universally true and adjust their goals and views on learning.

Educators must be deliberate and specific in the feedback that is provided, even being explicit about the phases of effective self-regulated learning that should be developed. Educators become a resource as trainees learn to develop appropriate goals and establish a plan forward. Determining the existing level of the learner and learning preferences of the trainee is essential for educators so that they can guide the learner toward suitable challenges that will scaffold him/her to the next level.

Advanced Beginner

For the advanced beginner, emphasis is on gaining practical experiences and knowledge. The balance tilts from taking textbook knowledge and applying it to the context, to better understanding the context, patient indicators, and beginning to discern and apply rules. Although perception is improving, judgments are still quite limited. The advanced beginner continues to be rational and analytic, but now sees actions as related rather than a series of independent steps.²⁴ Developing an understanding of connectedness helps learners realize the complexity of situations and with that comes an appreciation for how much they do not know (conscious incompetence).²⁵

Faculty provide trainees with structured opportunities and directly observe their skills. Under this closely guided practical experience, trainees assist with performing a procedure and receive some opportunities to try simpler tasks on their own. There is a high likelihood these trainees will be able to accomplish these simpler tasks successfully. With the learner starting to see steps as related, this is an opportunity for the educator to give feedback that will push the learner to be aware of more complex connections. Learners still require supervision for the procedure largely because they continue to have difficulty with troubleshooting. Educators should provide challenges just at the edge of the learners comfort level. The trainee's performance will help the educator identify where emphasis needs to be placed in the next educational encounter. It is important to debrief this experience with the learner so s/he can reflect back on emotions, thinking, and skills and establish subsequent goals. Educators simultaneously assess how much scaffolding learners require to extend them to the next level while also removing scaffolds as the learner demonstrates task competence.

Competent

At the competent level, the learner has well-developed conceptual models and fund of knowledge in a specialty. Although still primarily rational and analytic in decision-making, the learner is largely led by guidelines that are specific to the given context. In other words, through deliberate planning and judgment, the trainee can see the larger context and handle complex situations.²⁴ Trainees recognize what they know, for example, the limits of what they are able to troubleshoot on their own, and also know when to ask for guidance or help (conscious competence).²⁵ Safely progressing in a high-stakes environment while knowing when to slow down or stop is indicative of being able to reflect while in the moment. A competent level learner will reflect on actions and develop long-term goals.

Educators recognize that learners are able to complete an entire procedure independently to an optimal level. Nevertheless, educators still provide direct supervision to guide refinement, efficiencies, and standardization of procedures. With increasingly complex skills, educators will model specific methods. Learners at the competent stage ask for feedback and the response of the educator becomes less about general principles and more about fostering specific opportunities for individualized growth. While still under direct supervision, individualized instruction allows faculty to release greater degrees of responsibility for the full spectrum of patient care to residents/fellows so they can begin to take ownership and think ahead in developing a care plan.

Proficient

The proficient level represents a learner who sees context, actions, and interactions holistically. Physician core competencies (e.g., Patient Care and Professionalism), as outlined by the ACGME, are understood and enacted in an integrated way into the roles and responsibilities of the learner.⁶ It is in

seeing the bigger picture that the trainee is able to filter out extraneous materials and focus on essential information that results in less labored decision-making and consistently high levels of performance.²⁴ Residents/fellows are able to apply the depth of knowledge they have acquired in their specialty and increasingly become more intuitive with less dependence on rules (unconscious competence).²⁵ Trainees continue to be guided by maxims and rationale approaches to address unusual problems or deviations from expected patterns. The trainee reflects on personal performance with the goal of being able to efficiently merge intuitive and rationale approaches in complex situations.

Proficient residents/fellows have demonstrated that they reliably perform at an acceptable standard; therefore, there is a greater degree of indirect supervision. The role of faculty is to provide opportunities for learners to take full responsibility for performing a procedure, as well as work through uncommon cases. The feedback provided to learners is specific and formative (i.e., not scored) in helping them reach self-identified goals, as well as extend their critical thinking to unique problems and situations.

Expert

At the expert level, individuals have deep holistic understanding in their specialty. Depth of knowledge has provided them with intuitive understanding, confidence in decision-making, and ability to successfully manage complex situations with ease.²⁴ When faced with novel situations, they are able to seamlessly proceed with alternative approaches, consciously draw on guidelines and maxims, and consider innovative possibilities. Internal creative inquiry challenges these individuals to raise questions to themselves, put the mental brakes on what is familiar, and set goals that extend the field in new directions.²⁶ Experts are thought to be authorities in their specialties.

Individuals at this level rarely receive feedback unless they ask for it.²⁷ They adjust and adapt their learning with regular review of current literature, participating in CME, and pursuing and publishing research. As surgeons who independently perform procedures without any supervision, experts also rely on patient outcomes – by reflecting *in* action (e.g., adapting to unexpected conditions) and reflecting *on* action (e.g., follow-up care with patient) – as forms of feedback to inform practice.^{13,28} The expert level does not represent completion in learning, rather it signifies that a learner has the skills to continue to stay informed through workplace-based learning. This transition into habitual, ongoing, life-wide learning illustrates that a learner has solidified skills for lifelong learning.

SELF-REGULATED LEARNING AND LIFELONG LEARNING IN SURGERY EDUCATION

3 4 The purpose of this discussion is to show that skills for self-regulated learning can be learned, developed, and transformed into lifelong learning. The Dreyfus model provides an accessible model for visualizing the development and progression of skills from self-regulated learning into lifelong learning. The implications for overlooking development of lifelong learning skills are less obvious while under the observation and guidance of a Surgery Education program. However, if the goal of Surgery Education programs is to produce surgeons who are able to practice independently, actively pursue safe patient care with up-to-date knowledge and skills, then the development of skills for lifelong learning cannot be easily overlooked while still in training. As such, the role of faculty educators to model and explicitly teach about self-regulated learning and lifelong learning is essential.

Educators of residents/fellows at early levels of skill development must be explicit and concrete when explaining how to set independent goals for advancing abilities, as well as provide specific instructions on how to pursue inquiry on their own. As trainees deepen their skills and apply those more routinely, the responsibility for stimulating habitual inquiry begins to shift from the faculty to the trainee. The faculty now looks for the ways in which surgeons in training seek, receive, and provide feedback as indicators of the awareness learners have about where they need to focus their attention for growth.²⁹ With still further development of self-regulated learning, learners will likely transition into lifelong learners.

5 When advancing in training and moving into careers as experts, there is a great deal of familiarity with procedures, processes, and knowledge. When there is unconscious competence or deep understanding, automaticity sets in. Individuals at this level have ingrained skills and habits that routinely incite internal creative inquiry causing them to challenge these familiar patterns. The lifelong learner purposefully “makes unconventional linkages (...) in order to reveal unseen aspects.”²⁶ The

lifelong learner also seeks, applies, and makes new meaning. These are the surgeons who are prepared to deal with the problems of today, but even better prepared to deal with complexities that are yet to be encountered.

Chapter 2

Principles of Intermediary Metabolism

Steven E. Raper

Key Points

- 1 Intermediary metabolic pathways – the metabolic manipulation and balancing of ingested carbohydrate, fat, and protein – can process essentially all nutrients to acetyl coenzyme A (CoA) for energy production predominantly through aerobic glycolysis, the citric acid cycle, and oxidative phosphorylation.
 - 2 Glucose must always be available for brain function; if not available directly from the diet, it can be mobilized for a brief period from glycogen stores and then derived from proteins in the liver and kidneys.
 - 3 Free fatty acids are a direct source of energy for cardiac and skeletal muscles.
 - 4 Hepatic protein synthesis, when excess amino acids are available, includes albumin, fibrinogen, and apolipoproteins and can reach 50 g/day.
 - 5 The citric acid cycle includes a series of mitochondrial enzymes that transform acetyl CoA – itself derived from pyruvate or fatty acyl CoA – into water, carbon dioxide, and hydrogen-reducing equivalents. Each molecule of acetyl CoA that enters the citric acid cycle yields 12 molecules of adenosine triphosphate (ATP).
 - 6 Oxidative phosphorylation converts the energy from NADH and FADH₂ into ATP by the electron transport chain and ATP synthase with a process called the proton motive force.
 - 7 Biotransformation of potentially toxic, often hydrophobic, compounds into hydrophilic, excretable compounds occurs mainly in the liver by the cytochromes P-450, the uridine diphosphate-glucuronyl (UDP-glucuronyl) transferases, the glutathione (GSH) S-transferases, and the sulfotransferases.
-

INTERMEDIARY METABOLISM: AN OVERVIEW

Introduction

Intermediary *metabolism* – derived from the Greek word for change – is predominantly the fate of dietary carbohydrate, fat, and protein in a series of life-sustaining cellular chemical transformations. Although admittedly intricate, all surgeons should be familiar with the basics of the biochemistry by which nutrients are converted to energy. Understanding the major biochemical pathways is a prerequisite to making use of the rapid – and exciting – expansion of medical knowledge directed at managing human metabolic derangement and improving health by beginning at the cellular level.

1 Intermediary metabolic pathways – the metabolic manipulation and balancing of ingested carbohydrate, fat, and protein – can process essentially all nutrients to acetyl coenzyme A (CoA) for energy production predominantly through aerobic glycolysis, the citric acid cycle, and oxidative phosphorylation. The major intermediary metabolites are glucose, fatty acids, glycerol, and amino acids. Glucose is metabolized to pyruvate and lactate by glycolysis. Aerobic metabolism allows conversion of pyruvate to acetyl CoA. Acetyl CoA enters the citric acid cycle resulting in carbon dioxide, water, and hydrogen-reducing equivalents (a major source of adenosine triphosphate [ATP]). In the absence of oxygen, glycolysis ends in lactate. Glucose can be stored as or created from glycogen. Glucose can also enter the phosphogluconate pathway, where it is converted to reducing equivalents for fatty acid synthesis and ribose five-carbon sugars important in nucleotide formation. Glucose can be converted into glycerol for fat formation and pyruvate for amino acid synthesis. Gluconeogenesis allows synthesis of glucose from lactate, amino acids, and glycerol.

With regard to lipid metabolism, long-chain fatty acids arise from dietary fat or synthesized from acetyl CoA. Fatty acids can be oxidized to acetyl CoA by the process of beta-oxidation or converted to

acylglycerols (fat) for storage as the main energy reserve. In addition to the fats noted previously, acetyl CoA can be used as a precursor to cholesterol and other steroids and in the liver can form the ketone bodies, acetoacetate and 3-hydroxybutyrate, which are critical sources of energy during periods of starvation.

Proteins are degraded in two major ways: an energy independent path, usually in lysosomes, and an energy requiring path, usually through the ubiquitin pathway. About three-fourths of the amino acids generated in protein catabolism are reutilized for protein synthesis and one-fourth is deaminated to form ammonia and subsequently urea. Amino acids may be divided into nutritionally essential and nonessential. Nonessential amino acids require fewer enzymatic reactions from amphibolic intermediates or essential amino acids. Each day, humans turn over 1% to 2% of total body protein.

CARBOHYDRATE METABOLISM

The products of intestinal carbohydrate digestion are glucose (80%) and fructose and galactose (20%). Fructose and galactose are rapidly converted to glucose, and the body uses glucose as the primary molecule for transport and uptake of carbohydrates by cells throughout the body. Despite wide fluctuations in dietary intake, blood glucose levels are tightly regulated by the liver. About 90% of portal venous glucose is removed from the blood by liver cells through carrier-facilitated diffusion. Large numbers of carrier molecules on the sinusoidal surface of the hepatocyte are capable of binding glucose and transferring it to the cytoplasm. The rate of glucose transport is enhanced (up to 10-fold) by insulin. Given the critical role of glucose in survival, complex metabolic pathways have evolved for the storage of glucose in the fed state, the release of glucose from glycogen, and the synthesis of new glucose.

Blood glucose is stored, primarily in liver and muscle, as glycogen. Glycogen is a complex polymer of glucose with an average molecular weight of 5 million. The liver can convert up to 100 g of glucose into glycogen per day by glycogenesis. The liver can also release glucose into the blood by glycogenolysis, (breakdown of glycogen), or gluconeogenesis, (formation of new glucose from substrates such as alanine, lactate, or glycerol). Hormones play a key role in the hepatic regulation of glycogen balance. Insulin, for example, stimulates glycogenesis and glycolysis; glucagon stimulates glycogenolysis and gluconeogenesis through cyclic adenosine monophosphate (AMP) and protein kinase A.¹

Glycogenesis and Glycogenolysis

2 Glucose must always be available for brain function; if not available directly from the diet, it can be mobilized for a brief period from glycogen stores and then derived from proteins in the liver and kidneys. The first step in glycogen storage is the transport of glucose through the plasma membrane. Once in the hepatocyte, glucose and ATP are converted by the enzyme glucokinase to glucose-6-phosphate (G6P), the first intermediate in the synthesis of glycogen (Fig. 2-1). Because complete oxidation of one molecule of G6P generates 37 molecules of ATP, and storage uses only one molecule of ATP, the overall efficiency of glucose storage as glycogen is a remarkable 97%.

Glycogenolysis does not occur by simple reversal of glycogenesis. Each glucose molecule on a glycogen chain is released by glycogen phosphorylase (Fig. 2-2). Eventually, G6P is reformed. G6P cannot exit from cells and must first be converted back to glucose. The conversion of G6P to glucose is catalyzed by glucose-6-phosphatase, which exists only in hepatocytes, kidney, and intestinal epithelial cells. Brain and muscle both use glucose as a primary fuel source and do not contain the phosphatase enzyme. This lack of glucose-6-phosphatase ensures a ready supply of glucose for the energy needs of brain and muscle. Liver uses glucose primarily as a precursor for other molecules and not for fuel.

Glycolysis

Glycolysis is the mammalian cellular pathway by which glucose is converted to pyruvate or lactate (Fig. 2-3). The glycolytic pathway is interesting in that glucose can be metabolized in the presence (aerobic) or absence (anaerobic) of oxygen. Aerobic glycolysis is one of four stages in the oxidation of glucose and the only stage that occurs in the cytosol. As will be discussed below, stages II to IV occur in mitochondria; the citric acid cycle, electron transport generation of the proton motive force, and ATP synthase leading to generation of ATP.

Figure 2-1. The chemical reactions of glycogenesis and glycogenolysis. Glucose-6-phosphatase allows hepatic glucose to be transported out of the hepatocyte for use in other tissues. Glucose-6-phosphate, in *red*, plays a central role in carbohydrate metabolism.

Figure 2-2. Glucagon-stimulated enzyme cascade, responsible for the control of glycogen metabolism. Inactive forms are shown in *black*, active forms in *blue*.

The aerobic conversion of glucose to pyruvate has three effects: (a) a net gain of two ATP molecules, (b) generation of two reducing equivalents of the nicotinamide adenine nucleotide ($\text{NADH} + \text{H}^+$), and usually, (c) conversion of pyruvate to acetyl CoA with subsequent conversion of acetyl CoA in the mitochondria to ATP. The conversion of glucose to pyruvate is regulated by three enzymes: hexokinase (glucokinase), phosphofructokinase, and pyruvate kinase, which are nonequilibrium reactions and as such, functionally irreversible.

Under anaerobic conditions, NADH cannot be reoxidized by transfer of reducing equivalents through the electron transport chain to oxygen. Instead, pyruvate is reduced by NADH to lactate. Glycolysis takes place in the cytoplasm, in contrast to the citric acid cycle and oxidative phosphorylation which are mitochondrial processes. During times of glucose excess, as in the fed state, hepatic glycolysis can generate energy in the form of ATP, but the oxidation of ketoacids is a preferred energy source in liver.

The conversion of lactate (through pyruvate) to glucose – a process possible only in the presence of oxygen – is an important means of preventing severe lactic acidosis. Active skeletal muscles and erythrocytes form large quantities of lactate. In patients with large wounds, lactate also accumulates. The liver is exceptionally efficient at converting lactate to pyruvate through the Cori cycle (Fig. 2-4). As a result, one would expect that only significant liver dysfunction would affect the Cori cycle and lead to hyperlactatemia. However, lactate levels are now widely used to assess shock – septic and otherwise.²

The hypothesis is that circulatory hypoperfusion impairs tissue oxygen delivery with resultant mitochondrial hypoxia. In the absence of adequate oxygen, mitochondria switch to anaerobic glycolysis and oxidative phosphorylation stops. As a result, serum lactate concentrations appear proportional to ongoing tissue oxygenation deficits; thus improved lactate clearance can be used as a surrogate for success of sepsis therapy.³ Serum lactate can also be used to assess prognosis and triage patients to ICU level care.⁴

Figure 2-3. The glycolytic pathway. There is a net gain of two ATP molecules per glucose molecule. Phosphofructokinase is the key regulatory enzyme in this pathway; however, all the enzymes in *red* catalyze irreversible reactions. The pathway shown here is active only in the presence of aerobic conditions.

In erythrocytes, a unique variant of glycolysis enhances oxyhemoglobin dissociation. The first site in glycolysis for generation of ATP is bypassed, leading to the formation of 2,3-bisphosphoglycerate by an additional enzyme called bisphosphoglycerate mutase. Kinetics of the mutase present in erythrocytes allow the presence of high concentrations of 2,3-bisphosphoglycerate to build up. The 2,3-bisphosphoglycerate displaces oxygen from hemoglobin, allowing a shift of the oxyhemoglobin dissociation curve to the right.

Gluconeogenesis

There is an absolute minimum requirement for glucose in humans. Below a certain blood glucose concentration, brain dysfunction causes coma and death. When glucose becomes scarce, as in the fasting state, glycogenolysis occurs. Once glycogen stores have been depleted, the liver and kidneys are capable of synthesizing new glucose by the process of gluconeogenesis. Glucagon is produced in response to low blood sugar levels and stimulates gluconeogenesis.

Figure 2-4. The gluconeogenesis pathway. The irreversible nature of the glycolytic pathway means that a different sequence of biosyntheses is required for glucose production. The enzymes in *red* catalyze irreversible reactions that are different from those in glycolysis. In mammals, glucose cannot be synthesized from acetyl coenzyme A, only from cytosolic pyruvate.

Gluconeogenesis is not a simple reversal of the glycolytic pathway. In glycolysis, as noted previously, the conversion of glucose to pyruvate is a one-way reaction. As a result, four separate, functionally irreversible enzyme reactions are required to convert pyruvate into glucose (Fig. 2-5). These enzymes are pyruvate carboxylase, phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Other enzymes are shared with the glycolytic pathway.

About 60% of the naturally occurring amino acids, glycerol, or lactate can also be used as substrates for glucose production. Alanine is the amino acid most easily converted into glucose. Simple deamination allows conversion to pyruvate, which is subsequently converted to glucose. Other amino acids can be converted into three-, four-, or five-carbon sugars and then enter the phosphogluconate pathway (next section). Gluconeogenesis is enhanced by fasting, critical illness, and periods of anaerobic metabolism.

Figure 2-5. The Cori cycle, an elegant mechanism for the hepatic conversion of muscle lactate into new glucose. Pyruvate plays a key role in this process.

Phosphogluconate Pathway

When glucose enters the liver, glycogen is formed until the hepatic glycogen capacity is reached (about 100 g). If excess glucose is still available, the liver converts it to fat by the phosphogluconate pathway (also known as the pentose phosphate pathway) (Fig. 2-6). The cytosolic phosphogluconate pathway can completely oxidize glucose, generating CO_2 and nicotinamide adenine dinucleotide phosphate (NADPH) through what is known as the oxidative phase. Hydrogen atoms released in the phosphogluconate pathway combine with oxidized nicotinamide adenine dinucleotide phosphate (NADP^+) to form reduced nicotinamide adenine dinucleotide phosphate ($\text{NADPH} - \text{H}^+$).⁵ The oxidative phase is present only in tissues, such as the adrenal glands and gonads, that require reductive biosyntheses such as steroidogenesis or other forms of lipid synthesis. Essentially, all tissues contain the nonoxidative phase, which is reversible and produces ribose precursors for nucleotide synthesis. In erythrocytes, the phosphogluconate pathway provides reducing equivalents for the production of reduced glutathione by glutathione reductase. Reduced glutathione can remove hydrogen peroxide, which increases the conversion of oxyhemoglobin to methemoglobin and subsequent hemolysis.

LIPID METABOLISM

Lipid Transport

Lipid transport throughout the body is made complicated by the fact that lipids are insoluble in water. To overcome this physicochemical incompatibility, dietary triglycerides are first split into monoglycerides and fatty acids by the action of intestinal lipases. After absorption into small intestinal cells, triacylglycerols are reformed and aggregate into chylomicrons, which then enter the bloodstream by way of lymph. Chylomicrons are removed from the blood by the liver and adipose tissue. The capillary surface of the liver contains large amounts of lipoprotein lipase, which hydrolyzes triglycerides into fatty acids and glycerol. The fatty acids freely diffuse into hepatocytes for further metabolism. Similar to chylomicrons, very low-density lipoproteins (VLDLs) are synthesized by the liver and are the main vehicle for transport of triacylglycerols to extrahepatic tissues. The intestines and liver are the only two tissues capable of secreting lipid particles. In addition to chylomicrons and VLDLs, there are two other major groups of plasma lipoproteins: low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs). LDLs and HDLs contain predominantly cholesterol and phospholipid.

Figure 2-6. The phosphogluconate pathway. One of the major purposes of this pathway is to generate reduced nicotinamide adenine dinucleotide, which can serve as an electron donor and allow the liver to perform reductive biosynthesis. Glucose-6-phosphate, in red, plays a central role in carbohydrate metabolism.

The structure of all classes of lipoproteins is similar. There is a core of nonpolar lipids, either triacylglycerols or cholesteryl esters, depending on the particular lipoprotein. This nonpolar core is coated with a surface layer of amphipathic phospholipid or cholesterol oriented so that the polar ends are in contact with the plasma. A protein component is also present. The A apolipoproteins occur in

chylomicrons and HDLs. The B apolipoproteins come in two forms: B-100 is the predominant apolipoprotein of LDLs, whereas the shorter B-48 is located in chylomicrons. The C apolipoproteins can transfer between VLDLs, LDLs, and HDLs. Apolipoproteins D and E also exist. Apolipoproteins have several functions in lipid transport and storage. Some, such as the B apolipoproteins, are an integral part of the lipoprotein structure. Other apolipoproteins are enzyme cofactors, such as C-II for lipoprotein lipase. Lastly, the apolipoproteins act as ligands for cell surface receptors. As an example, both B-100 and E serve as ligands for the LDL receptor.⁶

Plasma variations in LDL cholesterol, HDL cholesterol, and triglycerides affect risk for atherosclerotic cardiovascular disease. As dyslipidemias are being identified and studied, new therapeutic approaches are needed. A convergence of human genetics and functional biology has led to recent advances in the study of lipoprotein metabolism. Genome-wide association studies have identified about 100 genes associated with plasma lipid phenotypes – many of which were not previously known to be associated with lipids. These genes are now being functionally validated through human genetic analysis such as deep targeted resequencing of kindreds with Mendelian lipid abnormalities or gene manipulation (over- or underexpression) in cultured cells and animal models.⁷

FATTY ACID METABOLISM

Most human fatty acids in plasma are long-chain acids (C-16 to C-20). Because long-chain fatty acids are not readily absorbed by the intestinal mucosa, they must first be incorporated into chylomicrons. In contrast, short-chain and medium-chain fatty acids are absorbed directly into the portal circulation and are avidly taken up by the liver. Free fatty acids in the circulation are noncovalently bound to albumin and are transferred to the hepatocyte cytosol by way of fatty acid-binding proteins. Fatty acid-CoA esters are synthesized in the cytosol after hepatic uptake of fatty acids. These fatty acid-CoA esters can be converted into triglyceride, transported into mitochondria for the production of acetyl CoA and reducing equivalents, or stored in the liver as triglycerides. The rate-limiting step in the synthesis of triglyceride is the conversion of acetyl CoA to malonyl CoA. Malonyl CoA, in turn, inhibits the mitochondrial uptake of fatty acid-CoA ester, favoring triglyceride synthesis. The liver also contains dehydrogenases that can unsaturate essential dietary fatty acids. Structural elements of all tissues contain significant amounts of unsaturated fats, and the liver is responsible for the production of these unsaturated fatty acids. As another example, dietary linoleic acid is elongated and dehydrogenated to the prostaglandin precursor arachidonic acid.

Figure 2-7. Diagram of hepatic fatty acid metabolism. Both dietary and newly synthesized fatty acids are esterified and subsequently degraded in the mitochondria for energy, first as reducing equivalents, then adenosine triphosphate via the electron transport chain. Acetyl CoA, in red, plays a central role in lipid metabolism.

3 Free fatty acids are a direct source of energy for cardiac and skeletal muscles and under basal conditions, most free fatty acids are catabolized for energy. Under conditions of adipocyte lipolysis, the liver can take up and metabolize fatty acids. Although fatty acid synthesis occurs in the cytosol, fatty acid oxidation occurs in the mitochondria. Fatty acid-CoA esters bind carnitine, a carrier molecule, and in the absence of cytosolic malonyl CoA, they enter the mitochondria, where they undergo beta-oxidation to acetyl CoA and reducing equivalents (Fig. 2-7). Acetyl CoA can then take one of the following routes: (a) enter the tricarboxylic acid cycle and be degraded to carbon dioxide, (b) be converted to citrate for fatty acid synthesis, or (c) be converted into 3-hydroxy-3-methylglutaryl CoA (HMG-CoA), a precursor of cholesterol and ketone bodies. The mitochondrial hydrolysis of fatty acids is a source of large quantities of ATP. The conversion of stearic acid to carbon dioxide and water, for instance, generates 136 molecules of ATP and demonstrates the highly efficient storage of energy as fat. By a process called beta-oxidation, acetyl-CoA molecules are cleaved from fatty acids. The acetyl CoA is then metabolized through the citric acid cycle under normal circumstances.

In times of significant lipolysis – starvation, uncontrolled diabetes, or other conditions of triglyceride mobilization from adipocyte stores – the predominant ketone bodies 3-hydroxybutyrate and acetoacetate are formed in hepatic mitochondria from free fatty acids and are a source of energy for extrahepatic tissues. Ketogenesis is regulated primarily by the rate of mobilization of free fatty acids. Once in the liver mitochondria, the relative proportion of acyl CoA destined to undergo beta-oxidation is limited by the activity of an enzyme, carnitine palmitoyltransferase-1. Lastly, there are mechanisms that keep the levels of acetyl CoA entering the citric acid cycle constant, so that only at high mitochondrial levels will acetyl CoA be converted to ketone bodies. Even the brain, in times of starvation, can use ketone bodies for half of its energy requirements. At some point, however, the ability of liver to perform beta-oxidation may be inadequate. Under such circumstances, hepatic storage of triglyceride or fatty infiltration of the liver can be significant, leading to the development of nonalcoholic steatohepatitis. Triglyceride storage by itself does not appear to be a cause of hepatic fibrosis, but fatty infiltration may be a marker for the derangement of normal processes by alcohol or

drug toxicity, diabetes, or long-term total parenteral nutrition. A specific type of microvesicular fatty accumulation is also seen in a variety of diseases, such as Reye syndrome, morbid obesity, and acute fatty liver of pregnancy.

Figure 2-8. The LDL receptor, an example of a transmembrane receptor that participates in receptor-mediated endocytosis. The LDL receptor specifically binds lipoproteins that contain apolipoprotein B-100 or E. Once internalized, the lipoproteins are degraded. AA, amino acids; EGF, epidermal growth factor.

As noted above, fatty acids are critical elements of all mammalian cells; as energy substrate, in cellular structure, and for intracellular signaling. Evolutionarily, storage of excess fat in adipose tissue mitigated starvation. But in most modern societies the ready availability of calorie-dense foods has led to an epidemic of obesity as is discussed in detail in other chapters. In terms of intermediary metabolism, excess dietary fatty acids are now known to cause insulin resistance in muscle through intramyocellular triglyceride content leading to type II diabetes. This effect is likely due to intracellular perturbations in active lipid metabolites such as diacylglycerols or ceramides. Other studies have documented mitochondrial abnormalities possibly through interference with serine kinases.⁸

CHOLESTEROL METABOLISM

Cholesterol is an important regulator of membrane fluidity and is a substrate for bile acid and steroid hormone synthesis. Cholesterol may be available by dietary intake or by de novo synthesis. In mammals, mostly new cholesterol is synthesized in the liver from its precursor, acetyl CoA. Dietary cholesterol intake can suppress endogenous synthesis by inhibiting the rate-limiting enzyme in the cholesterol biosynthetic pathway, HMG-CoA reductase. A competitive antagonist, lovastatin, can also block HMG-CoA reductase and effectively lower plasma cholesterol by blocking cholesterol synthesis, stimulating LDL receptor synthesis, and allowing an increased hepatic uptake and metabolism of cholesterol-rich LDL lipoproteins. The structure of the LDL receptor is known and serves as a model for the structure and function of other cell membrane receptors (Fig. 2-8).

Cholesterol is lipophilic and hydrophobic, and most plasma cholesterol is in lipoproteins esterified with oleic or palmitic acid. The liver can process cholesterol esters from all classes of lipoproteins. Hepatocytes can also take up chylomicron remnants containing dietary cholesterol esters. Abnormally elevated levels of cholesterol in VLDLs or LDLs are associated with atherosclerosis, whereas high HDL levels are protective. Newly synthesized hepatic cholesterol is also used to synthesize bile acids for further intestinal absorption of dietary fats. A large proportion of the bile acids secreted by the liver

into bile are returned to the liver via the enterohepatic circulation (Fig. 2-9).

Phospholipids

The three major classes of phospholipids synthesized by the liver are lecithins, cephalins, and sphingomyelins. Although most cells in the body are capable of some phospholipid synthesis, the liver produces 90%. Phospholipid formation is controlled by the overall rate of fat metabolism and by the availability of choline and inositol. The main role of phospholipids of all types is to form plasma and organelle membranes. The amphiphilic nature of phospholipids makes them essential for reducing surface tension between membranes and surrounding fluids. Phosphatidylcholine, one of the lecithins, is the major biliary phospholipid and is important in promoting the secretion of free cholesterol into bile. Thromboplastin, one of the cephalins, is needed to initiate the clotting cascade. The sphingomyelins are necessary for the formation of the myelin nerve sheath.

Figure 2-9. The enterohepatic circulation of bile acids. The primary bile acids, cholic acid, and chenodeoxycholic acid, are synthesized in the liver from cholesterol. Deoxycholic acid and lithocholic acid are formed in the colon (*blue lines*) during bacterial degradation of the primary bile acids. All four bile acids are conjugated with glycine or taurine in the liver. Most of the lithocholic acid is also sulfated, which decreases reabsorption and increases fecal excretion. Bile acids are absorbed passively in the epithelium of the small and large intestine and actively in the distal ileum.

PROTEIN METABOLISM

Formation and Catabolism of Plasma Proteins

4 Hepatic protein synthesis, when excess amino acids are available, includes albumin, fibrinogen, and apolipoproteins and can reach 50 g/day. Of the total hepatic protein synthesized, 75% is destined for export in plasma. Most newly synthesized proteins are not stored in the liver, and the rate of protein synthesis is primarily determined by the intracellular levels of amino acids. The tertiary structure of many proteins undergoes posttranslational modification after they have been synthesized in the liver's rough endoplasmic reticulum (ER). Glycosylation, or the addition of carbohydrate moieties, occurs in the smooth ER. Sialation, or the addition of sialic acid, occurs in the Golgi. Glycosylation is important in allowing some proteins to bind with specific receptors for subsequent hepatic uptake and processing. Removal of sialic acid residues, or desialation, from the terminal galactose molecules of glycoproteins allows them to bind to the asialoglycoprotein (ASGP) receptor in the liver and undergo degradation. Desialation, therefore, is important in the clearance of senescent proteins from the plasma.

Intracellular proteases hydrolyze proteins into peptides, and the peptides are in turn hydrolyzed by peptidases. Ultimately, free amino acids are generated. Unlike carbohydrate and lipids, excess amino acids are degraded if they are not immediately reincorporated into new proteins. Protein degradation occurs primarily by one of two routes. ASGPs are internalized into lysosomes via receptor-mediated endocytosis. The lysosomal enzymes do not require ATP and are nonselective in their activities; more than 20 known hydrolytic enzymes are present in lysosomes. A second pathway involves the covalent attachment of ubiquitin, named for the fact that it exists in all mammalian cells, targeting proteins for destruction. This pathway is ATP dependent and generally is used for proteins with shorter half-lives.⁹

Amino Acid Synthesis

Essentially, all the end products of dietary protein digestion are amino acids, which are absorbed by the enterocytes into the portal circulation in an ionized state. Liver amino acid uptake occurs by one of several active transport mechanisms. Amino acids are not stored in the liver but are rapidly used in the production of plasma proteins, purines, heme proteins, and hormones. Under certain conditions, the

amine group is removed from amino acids, and the carbon chain is used for carbohydrate, lipid, or nonessential amino acid synthesis.¹⁰

Ten nutritionally essential amino acids must be obtained from dietary intake (Table 2-2). However, human tissues contain transferases, which convert the α -keto acids of leucine, valine, and isoleucine so that the corresponding α -keto acids can be used as dietary supplements. The remaining nutritionally nonessential amino acids can be synthesized in one to three enzyme-catalyzed reactions. Hydroxyproline and hydroxylysine do not have a corresponding tRNA and arise by posttranslational modification of proline or lysine by mixed function oxidases. Glutamate, glutamine, and proline are derived from the citric acid cycle intermediate α -ketoglutarate. Aspartate and asparagine are synthesized from oxaloacetate. Serine and glycine are synthesized from the glycolysis intermediate 3-phosphoglycerate. Cysteine and tyrosine are formed from essential amino acids (methionine and phenylalanine, respectively).¹¹

Table 2-1 Amino Acids Required by Adult Humans

Nutritionally Essential	Nutritionally Nonessential	
	Amino Acid	Precursor
Arginine	Alanine	Pyruvate
Histidine	Asparagine	Oxaloacetate
Isoleucine	Aspartate	Oxaloacetate
Leucine	Cysteine	Methionine
Lysine	Glutamate	α -Ketoglutarate
Methionine	Glutamine	α -Ketoglutarate
Phenylalanine	Glycine	3-Phosphoglycerate
Threonine	Hydroxyproline	α -Ketoglutarate
Tryptophan	Hydroxylysine	Lysine
Valine	Proline	α -Ketoglutarate
	Serine	3-Phosphoglycerate
	Tyrosine	Phenylalanine

Catabolism of Amino Acid Nitrogen

Ammonia, derived largely from the deamination of amino acids, is toxic to all mammalian cells. The ammonia formed as a result of the deamination of amino acids is detoxified by one of two routes.¹² The most important pathway involves the conversion of ammonia to urea by enzymes of the Krebs–Henseleit, or urea cycle, which occurs only in the liver (Fig. 2-10). A second route of ammonia metabolism involves synthesis of L-glutamine from ammonia and glutamate by renal glutamine synthetase.

CELLULAR ENERGY GENERATION

Overview and Stage I

5 The citric acid cycle includes a series of mitochondrial enzymes that transform acetyl CoA – itself derived from pyruvate or fatty acyl CoA – into water, carbon dioxide, and hydrogen-reducing equivalents. Each molecule of acetyl CoA that enters the citric acid cycle yields 12 molecules of ATP. The fundamental mechanism by which mammalian cells generate energy is the aerobic conversion of sugars and fatty acids into ATP. There are four stages with stage I – glycolysis – (see glycolysis above) beginning in the cytosol, converting glucose into two molecules of pyruvate. Also, cytosolic fatty acids are converted to fatty acyl CoA. Pyruvate and fatty acyl CoA are transported to the mitochondrial matrix and converted to acetyl CoA; generating the electron carriers NADH or FADH₂ as well as CO₂. In stage II, mitochondrial acetyl CoA enters the citric acid cycle further generating NADH, FADH₂, additional CO₂, and GTP. In stage III, oxygen is reduced to water via the electron transport chain using previously generated molecules of NADH and FADH₂ as electron donors. The electron transport chain causes hydrogen ions to move from the mitochondrial matrix to the intermembrane space generating a proton motive force. Lastly, in stage IV, ATP synthase uses energy generated by the proton motive force to generate large amounts of ATP.¹³

Stage II: The Citric Acid Cycle: Integration of Metabolic Pathways and Oxidation of Acetyl

CoA

One major function of the citric acid cycle (also known as the Krebs cycle or the tricarboxylic acid cycle) is to act as a common pathway for the oxidation of carbohydrate, lipid, and protein and generate energy in the form of ATP. Conversely, the citric acid cycle is important in gluconeogenesis, lipogenesis, and amino acid metabolism. In the fed state, a large proportion of ingested energy from foodstuffs is converted to glycogen or fat. The metabolism of sugars, fats, and proteins, then, allows adequate fuels for all tissue types under conditions from fed to fasting to starvation. The body accomplishes production of fuel substrates for organs and regulates intestinally absorbed nutrients for tissue consumption or storage by integrating three key metabolites: G6P, pyruvate, and acetyl CoA (Fig. 2-11). Each of these three simple chemical molecules can be extensively modified to allow a large number of metabolites.

Figure 2-10. The urea cycle. Ammonia entering the urea cycle is derived from protein and amino acid degradation in tissues (endogenous) and the colonic lumen (exogenous).

G6P can be stored as glycogen or converted into glucose, pyruvate, or ribose-5-phosphate (a nucleotide precursor). Pyruvate can be converted into lactate, alanine (and other amino acids), and acetyl CoA, or it can enter the tricarboxylic acid cycle by conversion to oxaloacetate. Acetyl CoA is converted to HMG-CoA (a cholesterol and ketone body precursor) or citrate (for fatty acid and triglyceride synthesis), or it is degraded to carbon dioxide and water for energy. In humans, acetyl CoA cannot be converted into pyruvate due to the irreversible reaction of pyruvate dehydrogenase. Thus, lipids cannot be converted into either carbohydrates or glucogenic amino acids.

Probably the most important citric acid cycle function is to oxidize acetyl CoA into CO_2 . The citric acid cycle is composed of a series of enzyme reactions that occur in the mitochondrial matrix and inner membrane. Here, acetyl CoA combines with oxaloacetate to form citrate. Through a series of subsequent enzymatic reactions involving both dehydrogenases and decarboxylases, citrate is catabolized to result in the generation of hydrogen-reducing equivalents and carbon dioxide (Fig. 2-12). With each revolution of the citric acid cycle, a molecule of acetyl CoA generates three molecules of the reduced coenzyme NADH, one molecule of the reduced coenzyme FADH_2 , and one molecule of GTP. The reduced coenzymes NADH and FADH_2 are charged with high-energy electrons that subsequently drive the electron transport chain of stage III to generate a hydrogen ion gradient. These reducing equivalents are transported to the inner mitochondrial membrane and the electron transport chain to generate more ATP. Each molecule of NADH is oxidized to yield three molecules of ATP, and each molecule of FADH_2 is oxidized to yield two molecules of ATP. One molecule of ATP is generated at the substrate level in the conversion of succinyl CoA to succinate; thus, the total molecule of ATP generated per molecule of acetyl CoA is 12.

Stages III and IV: Oxidative Phosphorylation

6 Oxidative phosphorylation converts the energy from NADH and FADH₂ into ATP by the electron transport chain and ATP synthase with a process called the proton motive force. The covalent bond energy in glucose and fatty acids is transferred into high-energy electrons in stages I (glycolysis) and II (citric acid cycle). Flow of these high-energy electrons from NADH and FADH₂ to oxygen, creating water, is coupled to transport of protons across the mitochondrial inner membrane from the matrix to the intermembrane space. Originally called Mitchell's chemiosmotic hypothesis, many researchers now refer to this process as the proton motive force. The voltage gradient caused by the transport of these protons, and the ATP subsequently generated is the process known as oxidative phosphorylation. Below is an admittedly simplified explication of a complex process, and the stoichiometry of the reactions has been modified for clarity. Anyone interested in the precise biochemistry should consult the relevant sources (Fig. 2-13).

Two high-energy electrons carried by NADH or FADH₂ pass through three of four major multiprotein complexes: I – NADH-CoQ reductase; II – succinate-CoQ reductase; III – CoQH₂-cytochrome *c* reductase; and, IV – cytochrome *c* oxidase. The paths of NADH and FADH₂ are different initially. NADH electrons are transferred through complex I – NADH-CoQ reductase – to flavin mononucleotide (FMN), seven iron-sulfur clusters (Fe-S), and then coenzyme Q (CoQ) to create CoQH₂. Four protons are transported from the mitochondrial matrix as a result of the actions of complex I. Unlike NADH, FADH₂ is oxidized by complex II – succinate-CoQ reductase. The two FADH₂ electrons are transferred to succinate dehydrogenase-bound FAD when succinate is oxidized to fumarate, then an iron-sulfur cluster, and finally to CoQ creating CoQH₂.

Figure 2-11. Summation of the key regulatory molecules used by the liver during diverse metabolic functions. Essentially, any compound found in the body can be synthesized in the liver from glucose-6-phosphate, acetyl coenzyme A, or pyruvate. As a consequence of the inability of mammalian liver to convert acetyl coenzyme A to pyruvate, fats cannot be converted to carbohydrates.

Figure 2-12. The citric acid cycle. Reduced nicotinamide adenine dinucleotide and reduced flavin adenine dinucleotide, formed in the citric acid cycle, are subsequently oxidized in mitochondria by means of the electron transport chain to generate ATP. Acetyl CoA plays a key role.

CoQH₂ from NADH or FADH₂ is shuttled to complex III – CoQH₂-cytochrome *c* reductase – within the inner membrane. The two electrons are further transferred to cytochromes *b_L* and *b_H*, resulting in pumping of two additional hydrogen ions into the intermembranous space. Electrons are further transferred to another iron-sulfur cluster, cytochrome *c*₁, and ultimately the intermembranous space protein cytochrome *c*, pumping two additional hydrogen ions. Complex II catalyzes the conversion of fatty acyl CoA to acetyl CoA for further metabolism through the citric acid cycle. Cytochrome *c* shuttles the two electrons through the intermembranous space to complex IV – cytochrome *c* oxidase – reoxidizing the cytochrome *c* molecule, transferring the electrons to copper containing Cu_a, the heme moiety of cytochrome *a*₃, Cu_b, cytochrome *a*₃, and ultimately to oxygen, yielding water.

The net result of the electron transport chain is the pumping of ten H⁺ ions into the intermembranous space for two electrons flowing from NADH to O₂, and six H⁺ ions for each two electrons from FADH₂ to O₂. This generates the proton motive force; a voltage gradient across the inner mitochondrial membrane that directly provides energy for ATP generation in stage IV. ATP synthase harnesses the voltage gradient of protons across the inner membrane by interconverting the chemical potential energy into phosphoanhydride bonds of ATP. ATP synthase is composed of two main complexes: F₀, consisting of three types of membrane proteins, and F₁, a five-polypeptide complex protruding into the matrix.

Alternative Fuels

Regardless of the fed state of the human body, there is a requirement for glucose utilization. The nervous system and erythrocytes have an absolute requirement for glucose. Glucose is a source of glycerol-3-phosphate for adipose tissue, and most other tissues for integrity of the citric acid cycle. To maintain adequate glucose for survival, other fuels can be used depending on environmental conditions. Under conditions of carbohydrate shortage, ketone bodies and free fatty acids are utilized to spare oxidation of glucose in muscle. These alternate fuels increase intracellular citrate, which inhibits both phosphofructokinase and pyruvate dehydrogenase. In starvation, fatty acid oxidation results in the production of glycerol, which, along with gluconeogenesis from amino acids, is the only source of the

required glucose. Ultimately, even the brain can substitute ketone bodies for about half of its energy requirements.

The preferred energy substrates for liver are ketoacids derived from amino acid degradation even in well-fed states. This is designed to allow the consumption of glucose by obligate tissues. Glucose produced by the dephosphorylation of G6P rapidly diffuses out of the cell and is taken up by the brain, muscles, and other organs. Hepatic glycolysis is used primarily for the production of intermediates of metabolism and not for energy. Hepatic fatty acid degradation for energy is also inhibited under most circumstances and occurs only during adipocyte lipolysis. By way of clinical relevance, alterations in liver mitochondrial function are now known to be important in two common diseases. Patients with type 2 diabetes have reduced ATP synthesis and abnormal ATP repletion in response to substrate-induced ATP depletion. Nonalcoholic fatty liver disease is also associated with lowered ATP repletion in response to oxidative stress.¹⁴

Most short-, medium-, and long-chain fatty acids (C8 to C20) are metabolized by mitochondria to generate ATP. Mitochondria cannot metabolize fatty acids with acyl chains greater than 20, and these very long-chain fatty acids are metabolized in peroxisomes, predominantly in the liver. Peroxisomes do not contain elements of the citric acid cycle or electron transport chain and thus do not generate ATP. Most of the energy is released as heat.¹⁵

Adipocyte Phenotype, Thermogenesis, and Obesity

Epidemic obesity has created a surge of interest in the adipocyte, or fat cell. There are three basic types of adipocytes; white, brown, and beige. White adipocytes differentiate for the storage of fat and contain few mitochondria. The traditional view is that adult human fat is comprised predominantly of white adipocytes. These adipocytes accumulate lipid in times of over feeding leading to obesity and insulin resistance.⁸

Brown adipocytes are so named because of the brown color created by a high density of cellular mitochondria. Unlike the mitochondria of other organs, the mitochondria of brown adipocytes contain uncoupling protein-1 which can catalyze a protein leak across the inner membrane uncoupling electron transport from ATP synthesis. This results in the dissipation of energy as heat, or thermogenesis. Brown adipocytes were thought to be present only in human infants, and rare circumstances such as cold-climate outdoor workers or pheochromocytoma patients. Recently, the identification of “beige” adipocytes has led to the realization that the adipocyte may be a target for therapy of obesity. Beige adipocytes appear capable of switching from a white phenotype to brown, and the hope that adipocytes could be switched to utilize excess calories for thermogenesis rather than storage as fat.¹⁶

Figure 2-13. The electron transport chain. **A:** NADH pathway. Electrons flow through complex I to complex III via the lipid soluble molecule CoQ. From complex III, the electrons are transported through the intermembrane space by cytochrome c to complex IV. For every two electrons that flow from NADH to O₂, 10 protons are pumped to the intermembranous space. **B:** FADH₂-succinate pathway. Electrons flow through complex II to complex III via the lipid soluble molecule Coenzyme Q (CoQ). From complex III, the electrons are transported through the intermembranous space by cytochrome c to complex IV. For every two electrons that flow from FADH₂ and succinate to O₂, six protons are pumped to the intermembranous space.

BIOTRANSFORMATION

Biotransformation is defined as the intracellular metabolism of endogenous organic compounds (e.g., heme proteins and steroid hormones) and exogenous compounds (e.g., drugs and environmental

compounds). Most biotransformation occurs chiefly in the liver, which contains enzyme systems that can expose functional groups, such as hydroxyl ions (phase I reactions), or alter the size and solubility of a wide variety of organic and inorganic compounds by conjugation with small polar molecules (phase II reactions). A general strategy is to convert hydrophobic, potentially toxic compounds into hydrophilic conjugates that can then be excreted into bile or urine.

7 Biotransformation of potentially toxic, often hydrophobic, compounds into hydrophilic, excretable compounds occurs mainly in the liver by the cytochromes P-450, the uridine diphosphate-glucuronyl (UDP-glucuronyl) transferases, the GSH S-transferases, and the sulfotransferases. Biotransforming enzymes are not distributed uniformly within the cells of the hepatic lobule. This heterogeneity may account for the ability of some drugs to cause damage preferentially in zone 3 hepatocytes (those nearest the central venule).

Cytochromes P-450

The cytochromes P-450 are named for their ability to absorb light maximally at 450 nm in the presence of carbon monoxide. These enzymes are bound to the ER and collectively catalyze reactions by using NADPH and oxygen. The P-450 isozymes present in mammalian liver catalyze reactions such as oxidation, hydroxylation, sulfoxide formation, oxidative deamination, dealkylation, and dehalogenation. Such reactions allow further phase II conjugation with polar groups such as glucuronate, GSH, and sulfate. The cytochromes P-450 can also create potentially toxic metabolites. Drugs such as acetaminophen, isoniazid, halothane, and the phenothiazines can be converted into reactive forms that cause cellular injury and death. The cytochromes also are responsible for the formation of organic free radicals, reactive metabolites that can directly attack and injure cellular components or act as haptens in the generation of an autoimmune response. Several of the most potent known carcinogens are aromatic hydrocarbons, which are modified by cytochromes P-450.

Uridine Diphosphate-glucuronyl Transferases

Glucuronidation is the conjugation of UDP-glucuronic acid to a wide variety of xenobiotics by either ester (acyl) or ether linkages. The transferases catalyzing these reactions reside in the ER. Many common compounds are metabolized in this way, including bilirubin, testosterone, aspirin, indomethacin, acetaminophen, chloramphenicol, and oxazepam. Clinically significant loss of activity can occur with acute ethanol exposure or acetaminophen overdose, when formation of UDP-glucuronic acid from UDP-glucose is outstripped by use. Some acyl linkages lead to the generation of electrophilic centers that can react with other proteins. The covalent linkage of conjugated bilirubin to albumin is believed to occur by this mechanism.

Glutathione S-transferases

The GSH transferases are more selective in the biotransformations they perform. GSH conjugation occurs only with compounds that have electrophilic and potentially reactive centers. The role of GSH conjugation catalyzed by the GSH S-transferases is demonstrated by acetaminophen. In metabolism of this drug, cytochromes P-450 create an electrophilic center that reacts with protein thiol groups or GSH.¹⁷ The presence of GSH S-transferase allows the preferential detoxification of acetaminophen rather than its potentially injurious binding to thiol groups. A class of GSH S-transferases, known as *ligandins*, appears to facilitate the uptake and intracellular transport of bilirubin, heme, and bile acids from plasma to liver. In addition to the detoxification of potential toxins, GSH is a substrate for GSH peroxidase, an enzyme important in the metabolism of hydrogen peroxide.

Sulfotransferases

The sulfotransferases catalyze the transfer of sulfate groups from 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to compounds such as thyroxine, bile acids, isoproterenol, α -methyldopa, and acetaminophen. They are located primarily in the cytosol. Although many P-450 derivatives can be further conjugated by either the sulfotransferases or the glucuronyl transferases, a limited ability of the liver to synthesize PAPS makes glucuronidation the predominant mechanism.

HEME AND PORPHYRIN METABOLISM

Heme is formed from glycine and succinate and is the functional iron-containing center of hemoglobin,

myoglobin, cytochromes, catalases, and peroxidases. From glycine and succinate precursors, δ -aminolevulinic acid (δ -ALA) is synthesized by the rate-limiting enzyme ALA synthase. The porphyrinogens are intermediates in the pathway from δ -ALA to heme, and porphyrins are oxidized forms of porphyrinogen (Fig. 2-14). Inherited enzyme defects in the heme synthetic pathway cause the overproduction of various porphyrinogens, which can in turn cause clinical manifestations known as the *porphyrias*.¹⁸ Acquired porphyria can be caused by heavy metal intoxication, estrogens, alcohol, or environmental exposure to chlorinated hydrocarbons.

Bilirubin IXa is the predominant heme degradation product in humans and is derived mostly from hemoglobin. The enzyme heme oxygenase, located in cells of the reticuloendothelial system, is primarily responsible for this conversion. Heme oxygenase resides in the ER and requires NADPH as a cofactor. Hepatic processing of bilirubin is further detailed in the section on bile formation.

METAL METABOLISM

Iron uptake appears to occur by two distinct processes: (a) receptor-mediated endocytosis of iron–transferrin complexes and (b) facilitated diffusion across the plasma membrane. More iron is taken up and stored by the liver than by any other organ, with the exception of the bone marrow. Transferrin is synthesized in the liver and has specific plasma membrane receptors on a number of different tissues. After endocytosis, the transferrin and iron dissociate and the transferrin and transferrin receptors return to the cell surface for recycling. A pathway appears to involve the dissociation of iron and transferrin at the plasma membrane and subsequent internalization by carrier-mediated diffusion. Once internalized, iron is stored and forms a complex with apoferritin. Each apoferritin molecule is capable of storing several thousand iron molecules. The iron–apoferritin complex, called *ferritin*, is responsible for iron storage under physiologic conditions. Iron storage in a protein-bound form is essential because free iron can catalyze free radical formation, leading to cell injury.¹⁹

Figure 2-14. The heme biosynthetic pathway. Inherited defects of each of the heme biosynthetic enzymes except δ -aminolevulinic acid synthase have been described and lead to the clinical disorders known as the porphyrias.

Copper is transported to the liver bound to albumin or histidine and enters the hepatocytes by a process of facilitated diffusion. Once inside the cell, copper can bind to several intracellular proteins for storage or as a necessary enzyme cofactor. Copper-binding proteins include metallothionein, monoamine oxidase, cytochrome c oxidase, and superoxide dismutase. *Ceruloplasmin* is a liver-derived protein that binds hepatic copper for transport to other tissues. The low levels of ceruloplasmin seen in patients with Wilson disease suggest a pathogenetic defect.

Zinc is taken up by and competes for the same binding sites as copper. In hepatocytes, zinc binds predominantly to metallothionein and is excreted into bile, in which it enters the enterohepatic circulation. Other metals, usually found in trace amounts, are lead, cadmium, selenium, mercury, and nickel. These metals are usually bound to metallothionein or GSH, and intoxication is associated with free radical formation and liver injury.

SUMMARY

The broad brush-stroke fundamentals of intermediary metabolism have been known for years, however, knowledge on the details expands at an ever-increasing rate. A working understanding of the fundamental biochemical reactions by which substrates are metabolized is important for all surgical disciplines. Advanced knowledge of the genetics, cellular biology, bioenergetics, and molecular biology is being exploited to support and perhaps enhance general and specialized cellular function, combat disease, and improve health.

Chapter 3

Surgical Nutrition and Metabolism

George Kasotakis

Key Points

- 1 Starvation and systemic inflammatory response result in erosion of the fat-free mass and body weight (malnutrition) and are indicators for nutrition support if present.
 - 2 Inflammation increases energy utilization and alters the metabolism of glucose, protein, fat, and trace minerals.
 - 3 Hypermetabolism is seen in numerous disease states, and not merely in trauma and sepsis.
 - 4 Numerous methods exist to aid assessment of patients' nutritional status, each with its own advantages and disadvantages.
 - 5 A strong relation between protein depletion and postoperative complications has been demonstrated in nonseptic, nonimmunocompromised patients undergoing elective major gastrointestinal surgery.
 - 6 The main goal of perioperative or posttraumatic nutritional support is repletion or maintenance of protein, energy stores, and other nutrients to allow rapid and full recovery from illness.
 - 7 Whenever providing nutritional support, supply caloric intake in the form of carbohydrate and fat in a 2:1 ratio, if no contraindications exist.
 - 8 Enteral nutritional support is always preferable than parenteral nutrition, in the presence of a functioning gastrointestinal tract.
 - 9 The maintenance of an intact brush border and intercellular tight junctions prevents the movement of toxic substances into the intestinal circulation and minimizes bacterial translocation. These functions may be affected in critical illness. Enteral nutrition helps restore them.
 - 10 Allow hypocaloric enteral feedings in the acute phase of critical illness for up to 5 to 7 days in previously well-nourished patients. Start as early as feasible.
 - 11 Routine glutamine supplementation is not supported during critical illness.
 - 12 Supply micronutrients to prevent refeeding syndrome, and monitor electrolytes, liver function tests, and triglyceride levels as needed.
 - 13 The adequacy of nutritional support should be reassessed frequently and adjustments made as needed until full convalescence.
-

INTRODUCTION

Patients undergoing gastrointestinal procedures with evidence of malnutrition at baseline are more likely to suffer postoperative morbidity, mortality, and require longer hospital stays compared to their well-nourished counterparts.^{1,2} The problem is greater than most realize, with up to 14% of patients scheduled for elective gastrointestinal tract procedures found to be malnourished and up to 40% of those with gastrointestinal disease found to be at risk for malnutrition.³ It has been shown that poor nutritional status can detrimentally affect postoperative outcomes,⁴ and in a consensus review of Enhanced Recovery After Surgery, it was recommended that patients receive carbohydrate loading 24 hours preoperatively and nutritional supplements, from the day of surgery, until oral intake is achieved.⁵

In addition to patients undergoing elective surgery, severe injury and critical illness are associated with a hypermetabolic state that can increase energy expenditure dramatically and complicate the resuscitation and recovery of the critically ill or severe injury victim. Over the last few years, aggressive nutritional support has been underlined as an integral part of the caring of the critically ill surgical patient, and the Society for Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) have made recommendations toward providing early,

aggressive nutritional support that enables patients to preserve their immune function, maintain lean body mass, and minimize metabolic complications.^{6,7} This chapter addresses the areas of nutritional assessment and management of the surgical patient, reviewing key metabolic principles and providing an overview of pertinent literature.

BASIC METABOLIC PRINCIPLES

Body Composition

Total body mass is composed of aqueous and nonaqueous components, with the former constituting approximately 55% to 60% of total body mass (total body water, TBW). Mineralized bone and adipose tissue make up the majority of the nonaqueous component. The relationship between total body mass and TBW is relatively constant for an individual and typically reflects the amount of body fat. Solid organs and muscle contain a higher proportion of water than bone and fat, therefore young lean males have a higher proportion of their total body mass as water, compared to obese or elderly individuals. Obesity, older age, and female gender shift the body composition to a greater fat mass (Fig. 3-1).⁸

The aqueous portion is divided into three functional fluid compartments: plasma (5% of body weight), interstitial or extracellular fluid (ECF; 15% of body weight), and intracellular fluid (ICF; 40% of body weight) (Fig. 3-2). In a typical 70-kg male, there are approximately 3.5 L of plasma, 10.5 L of interstitial fluid, and 28 L of intracellular volume, while the remainder 28 kg represent the nonaqueous portion. Of the above, the body cell mass constitutes the metabolic engine of the body, while the extracellular component forms the supporting “scaffolding” for the body cell mass.

Figure 3-1. Body composition as a function of gender and age. (Data from Cohn SH, Vaartsky D, Yasumura S, et al. Compartmental body composition based on total-body nitrogen, potassium, and calcium. *Am J Physiol* 1980; 239:E524–E530.)

In clinical practice, body composition is inferred indirectly using the body mass index (BMI; kg/m²), which reflects the fatty proportion of the total body weight. According to the Centers for Disease Control and Prevention, a BMI between 25 and 29.9 kg/m² is indicative of being overweight, whereas an individual with a BMI of ≥ 30 kg/m² is considered obese.

Body composition may change acutely after trauma or major surgery.⁹ These changes are characterized by a rapid loss of lean body mass and expansion of the ECF compartment, the latter manifesting clinically as edema. The underlying changes in body cell mass and fat mass are difficult to recognize until much later in the process, when they manifest as temporal or extremity wasting. Tools to assess changes in body composition during critical illness have been described (arm circumference and tissue bioelectrical impedance), but their use and utility in daily clinical practice are limited.^{10–12}

Energy and Substrate Metabolism

Energy Production and Measurement

The human body functions much like an engine, in that it uses oxygen to burn fuel (carbohydrate, fat, and protein) and generate energy, excreting the byproducts of this combustion (carbon dioxide, water, urea, and heat) to the environment (Fig. 3-3). This energy, which is necessary for numerous functions of the human body, both on micro- (molecular synthesis and transport) and macroscopic (breathing and mobility) levels, is derived from the energy present in the chemical bonds of the nutrients consumed.

When no nutrition is provided, such as during periods of starvation or immediately after surgery or trauma, the body oxidizes stored fuel to generate energy.

Figure 3-2. Aqueous and nonaqueous body composition.

The energy production process is relatively inefficient, as approximately half of the nutrient-containing energy is eventually converted to heat, instead of all of it being utilized for work. Some of this heat is used to help maintain body temperature (via meticulously regulated hypothalamic mechanisms), while the remainder is released to the environment – mostly through the skin. During illness, or following surgery or trauma, the central temperature regulating mechanisms become reset, leading to the development of fever, usually an appropriate response to a physiologic stressor. This increase in body temperature typically intensifies the rate of enzymatic-facilitated chemical reactions that are essential to the inflammatory response.

All energy produced by the human body comes from oxidation of fuel via a series of decarboxylation/dehydrogenation reactions. The fuel undergoing oxidation is derived from food or mobilization of fuel stores. The energy released by these reactions is captured in adenosine triphosphate (ATP), the human body’s energy “coin,” via a series of redox reactions. In the final step of energy production from carbohydrates or fat, hydrogen is combined with oxygen to form water. The oxygen required and the carbon dioxide produced in this process are transported by the circulatory system and exchanged with the environment by the lungs. Protein oxidation is a special case, in which nitrogen is a byproduct, in addition to carbon dioxide and water. This nitrogen is removed by the kidneys, after conversion to urea by the liver.

Energy is measured in joules or calories. The joule is the SI unit of energy and is defined as the energy required to exert a force of 1 N for a distance of 1 m (unit of measure is kg/m²/s²). In the United States, energy is most commonly measured in g-calories (gram-calories) or kg-calories (kilo-calories or kcal). A g-calorie is the amount of heat required to raise the temperature of 1 g of water from 14.5°C to 15.5°C at the pressure of one standard atmosphere, whereas the kg-calorie is the amount of heat needed to increase the temperature of 1 kg of water under the same circumstances. Joules and g-calories are very small units of energy (1 J is expended by a resting person every hundredth of a second), therefore megajoules (MJ) and kilocalories are far more commonly used to describe energy produced from human nutrition. A megajoule is equivalent to 10⁶ J, while a kilocalorie is equivalent to 10³ calories. One megajoule corresponds to 239 kcal.

Figure 3-3. Fuel utilization in human metabolism.

CLASSIFICATION

Table 3-1 Fuel Reserves of a Healthy, 70-kg Adult Male

Energy Source	kg	kcal Value
Fat	14	125,000
Protein		
Skeletal muscle	6	24,000
Other	6	24,000
Glycogen		
Muscle	0.15	600
Liver	0.075	300
Free glucose	0.02	80

Body Fuels

Human metabolism is organized in such a way, so that fuel consumption occurs in a hierarchical way when more than one energy source is present, with excess stored for the postprandial or fasting period. In the postprandial state, the body contains fuel reserves that it can also mobilize in an orderly fashion, as fasting is prolonged. The same fuel reserves are accessed during stress metabolism, although in a less orderly fashion (Table 3-1).

Calorically dense fat is by far the largest energy repository, providing 9 kcal/g when mobilized and oxidized. The ability of the body to store fat is essentially limitless. Protein comprises the next largest energy store in the human body, yet amino acids when oxidized yield 4 kcal/g. And unlike fat, protein plays both a structural and functional role in the body, thus, in severe protein loss, major functional consequences can be expected. In malnutrition, proteolysis frees up amino acids to be used for gluconeogenesis to produce glucose, which in turn can be used as fuel. Carbohydrate reserves are minimal and exist in the form of glucose or glycogen in the liver. These can be depleted quickly, typically within 12 hours, unless replenished through nutrition. Carbohydrates, like protein, also yield approximately 4 kcal/g when mobilized for energy production (Table 3-2).

Carbohydrates. Carbohydrates are the most commonly used fuel by the human body, providing frequently over 45% to 60% of daily energy requirements. Each gram of carbohydrate that is administered enterally yields approximately 4 kcal when broken down, whereas intravenously administered carbohydrates (such as dextrose-containing solutions) provide slightly less (approximately 3.4 kcal/g).

Table 3-2 Energy Value of Various Energy Sources

Energy Source	Energy Value
Fat	9 kcal/g
Carbohydrates (enteral)	4 kcal/g
Carbohydrates (intravenous)	3.4 kcal/g
Protein	4 kcal/g

The basic unit of carbohydrate metabolism in humans is glucose, and nearly all dietary carbohydrates are converted to glucose for energy production. Digestion of carbohydrates begins as proximally as the oral cavity with food ingestion, where salivary amylase breaks down polysaccharides into smaller oligo- and disaccharides. This process continues in the duodenum and proximal jejunum with the pancreatic amylase. Oligosaccharidases that are present in the brush border of the proximal small bowel further hydrolyze oligosaccharides into di- or monosaccharides, most commonly glucose, to be absorbed by the gut mucosa. Once glucose reaches the bloodstream, it stimulates secretion of insulin from the endocrine pancreas (beta cells), which has major anabolic effects and stimulates protein synthesis, inhibits lipolysis, and upregulates glycogen production. Conversely, during stress, pancreatic glucagon exerts opposite effects: it promotes breakdown of glycogen, but also fat and protein, to be used as additional energy sources during a time when energy requirements are maximal. Deficiencies in carbohydrate digestion are rare in surgical patients, even in patients in whom the pancreatic exocrine function is significantly decreased. Patients with pre-existing celiac or Whipple disease may, however, have limited capacity to absorb carbohydrates.

The human central nervous system and circulating blood cells require glucose constantly for their energy requirements. In periods of extended fasting, after the liver has used up its stores of glycogen, the human body breaks down protein and uses the resulting amino acids to generate glucose, and even converts fat into ketones that can partly substitute glucose as an energy source. When glucose is reinstated through nutrition, these metabolic adaptations are completely reversed. During stress,

gluconeogenesis and glycogen breakdown is accelerated and ketone production minimized, leading to an abundance of glucose for use as the human body mounts an inflammatory response.

Lipids. Lipids are the second most commonly used fuel for energy by the human body, accounting for 35% to 45% of daily caloric intake. Each gram of fat yields approximately 9 kcal of energy when oxidized. When lipids enter the proximal small bowel, cholecystokinin and secretin are released, which make the gallbladder contract and release bile into the duodenum. Bile salts contained in bile are necessary for lipid absorption, especially the long-chain fatty acids that are found in a typical western diet, which occurs mostly in the distal ileum. Surgical resection of the distal ileum may lead to depletion of the bile salt pool and fat malabsorption.

Lipids are most commonly classified by the length of their contained hydrocarbon chains. Short-chain fatty acids typically refer to lipids containing 2 to 5 carbon length chains and are a product of dietary fiber fermentation in the colon by the intestinal flora. They are absorbed by and are the preferred fuel for the colonocytes. Medium-chain fatty acids (6 to 9 carbon length chains) are also not typically found in the human diet, but are commonly used in numerous enteral nutrition formulas, as they are easier to digest, compared to longer chain triglycerides. They are water soluble, and hence require no emulsification or micelle formation for transport. Lipase is not required. The medium-chain triglycerides are absorbed directly into the portal circulation. Unlike the short- and medium-chain fatty acids which can be produced from other dietary substrates, two long-chain fatty acids (>9 carbon length chains), linoleic and linolenic acids, are essential for human nutrition. These are not water soluble and require bile salts for emulsification as stated above, lipase for digestion, and micelle/chylomicron formation for transport. They gain access to the bloodstream via the lymphatic system (thoracic duct). Insufficient intake of these essential fats can lead to fatty acid deficiency, which can be prevented with provision of at least 3% to 4% of the daily calories as linoleic and linolenic acids. These two fatty acids are also a precursor of eicosanoids, significant mediators of the inflammatory response. On a cellular level, lipoprotein lipase is necessary for intake, and carnitine for transport from the cytosol into the mitochondria for oxidation. Long-chain triglycerides are the main form of energy storage in the human body, given the numerous high-energy bonds they contain.

Protein. Protein is different from carbohydrate and lipids in that it contains nitrogen that neither fatty acids nor glucose do. It is also a key structural component, and there are no inactive protein stores. Essentially all proteins are either functional or structural in the human body.

Proteins are polypeptides, containing numerous amino acids as their building blocks, and yield 4 kcal/g when used for energy production. Dietary protein is broken down into amino acids and smaller peptides by gastric pepsin and pancreatic proteases, the latter activated by enterokinase in the duodenum. These amino acids and oligopeptides get absorbed mostly in the proximal gastrointestinal tract and travel to the liver, where they are recycled to synthesize new protein. In a healthy, 70-kg weighing adult male over 300 g of protein are recycled daily. The branched-chain amino acids (BCAAs; leucine, isoleucine, and valine) are transported to muscle unaltered, while other amino acids are distributed to the intra- and extracellular pool for protein synthesis as needed. Excess amino acids are usually converted to glycogen or free fatty acids.

In addition to the dietary protein, intracellular proteins are continuously recycled, and the resulting free nitrogen is excreted, mostly through urine. Most of the urine nitrogen is in the form of urea (85%), with smaller amounts excreted as creatinine and ammonia. Urinary nitrogen decreases significantly with protein-free diets (decreased intake), but increases during stress (greater turnover).

Amino acid metabolism generates ammonia, a highly toxic compound, which is converted into urea (nontoxic) in the liver. Glutamine and alanine serve as ammonia-transporting vehicles in a nontoxic form from the metabolically active peripheral tissues to the viscera. There, ammonia is resynthesized and either excreted (by the kidneys, where it also acts as a buffering system) or detoxified to urea (liver). Diseases that affect the functional capacity of either the kidneys or the liver can lead to significant ammonia build up in the body, with potentially toxic consequences to the central nervous system.

Other Nutrients

To maintain health, in addition to energy, numerous other nutrients are required for the numerous metabolic functions of the human body. These include nucleotides, vitamins, and trace elements. The former are increasingly identified as important for the nutrition of the critically ill patient, whereas vitamins and trace elements are important for numerous anabolic functions.

Nucleotides. Nucleic acids are the building blocks for DNA and RNA, and are not typically considered essential for a balanced nutrition in healthy adults. However, dietary requirements become significant during severe stress and critical illness, as nucleic acids are necessary for rapidly proliferating cells, such as the cells participating in the immune function. Diets augmented with RNA or the nucleotide uracil have been shown to restore delayed hypersensitivity and improve the lymphoproliferative response. As such, they have been included in enteral nutrition formulas, where they may aid recovery from severe infections.¹³

Vitamins. Vitamins A, D, E, and K are fat soluble and are absorbed in the small bowel in association with long-chain fatty acids. From there, they are transported to the liver (vitamins A and K) or the skin and subcutaneous tissue (vitamins D and E) for storage. Fat-soluble vitamins are required for normal immune function and play a significant role in wound healing. Daily vitamin A intake in patients on chronic corticosteroid regimens may counteract most of steroid-mediated adverse effects of wound healing.

Unlike vitamins A, D, E, and K, vitamins B1, B2, B6, and B12, along with vitamin C, niacin, folate, biotin, and pantothenic acid are water soluble and are absorbed in the proximal small bowel. From there, they are transferred to the liver with the portal circulation for use or storage. Water-soluble vitamins are required for normal amino and nucleic acid metabolism.

Electrolytes and Trace Elements. Electrolytes are important components of both the intra- and extracellular compartment, where they play a major role in maintaining electrical and osmotic balance across the body's plasma membranes. Such electrolytes include sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), and are cations (with a positive charge) or anions (with a negative charge), due to uneven distribution of electrons. Sodium is the main extracellular electrolyte and is important in maintaining volume homeostasis and blood pressure control. Conversely, potassium is one of the key intracellular cations. The role of electrolytes is diverse, and includes functions as varied as the conduction of electric signals, cotransport of larger molecules against their concentration gradient, muscular contraction, and participation in numerous essential biochemical reactions.

Trace elements play an important role in numerous metabolic, immunologic, and healing functions and eight minerals have been identified as "essential." These include iron, iodine, zinc, chromium, copper, selenium, manganese, and molybdenum.

Iron is an integral component of the heme core in hemoglobin and of the mitochondrial cytochrome complex. Subtle impairments in central nervous, musculoskeletal, and immune system function can be identified in patients with iron deficiency, before microcytic anemia becomes clinically evident. Impaired cerebral, muscular, and immunologic function can occur in patients with iron deficiency before anemia becomes clinically evident. Particular attention has to be paid to pregnant and lactating females, in whom iron requirements are even greater than the rest of the population.

Iodine is a key component of the thyroidal hormonal system. Deficiencies are rare in the western world, due to widespread use of iodinated salt. However, chronically malnourished patients can develop significant iodine deficiency, which can typically manifest clinically as diffuse goiter and hypothyroidism.

Zinc deficiency can manifest with skin discoloration and perioral rash, neuritis, hair loss, and alterations in taste and smell. Chromium deficiency presents as impaired glucose tolerance during prolonged fasting and is fairly common with total parenteral nutrition (TPN). Copper deficiency presents with microcytic anemia, typically unresponsive to iron, abnormal skin keratinization, and, in its most severe cases, pancytopenia. Selenium deficiency, which can similarly be identified in cases of prolonged TPN administration, manifests as neuromuscular dysfunction or cardiac conduction defects, which in the most severe cases can lead to heart failure. Manganese deficiency can be identified as the underlying cause in a syndrome presenting as unintentional weight loss, hair color changes, and hypolipidemia. Molybdenum deficiency is associated with hypomethioninemia and hypouricemia, resulting in nausea and vomiting, tachycardia, and nonfocal central nervous system dysfunction (Table 3-3).

Nutritional Assessment

Metabolism is altered to varying degrees by stress, namely surgical injury, critical illness, infection, and physical trauma. In most cases, these alterations are short lived and reversible in a previously well-nourished individual, even if fasting is superimposed during acute illness. However, pre-existing

malnutrition, even if mild, and prolonged post-stressor fasting, intentional or not, can adversely affect healing, recovery, and overall outcomes after injury or surgery.^{14–20} In addition, the nutritional needs of a patient recovering from severe infection, injury, or a major operation are different than those of nonstressed individuals and aggressive postoperative or postinjury nutritional regimens are associated with improved outcomes.²¹ This recognition has led nutrition science to become an integral part of modern medicine and critical care, and nutritional support to continue to gain ground as primary therapy in the care of the surgical and critically ill patient.

Table 3-3 Summary of the Daily Requirements of Vitamins, Electrolytes, and Trace Elements in a per os Diet by Healthy Adults

Vitamins	
Retinol (vitamin A)	1,000 mcg
Thiamine (vitamin B1)	1.4 mg
Riboflavin (vitamin B2)	1.7 mg
Pyridoxine (vitamin B6)	2.2 mg
Ascorbic acid (vitamin C)	60 mg
Niacin	20 mg
Folate	200 mcg
Biotin	150 mcg
Pantothenic acid	4–7 mg
Retinol (vitamin A)	1 mg
Vitamin D	5 mcg
Vitamin E	10 mg
Vitamin K	75–150 mg
Electrolytes	
Sodium	90–150 mEq
Potassium	60–90 mEq
Calcium	1,300 mg
Magnesium	350 mg
Phosphorus	800 mg
Trace Elements	
Iron	10 mg
Iodine	150 mcg
Zinc	15 mg
Chromium	5–200 mcg
Copper	2–3 mg
Selenium	100 mcg
Manganese	2.5–5 mg
Molybdenum	100–500 mcg

Subjective Global Assessment

12 Subjective global assessment of a patient's nutritional status is commonly utilized to assess the presence and degree of malnutrition in surgical patients. It is one of the few clinical methods that has been validated as a reproducible method assessing a patient's nutritional status and has been consistently associated with clinical outcomes. This global assessment utilizes numerous variables, including physical examination and anthropometric measurements such as weight, height, and weight loss history; dietary questionnaires and portion size analyses; along with pertinent past medical history to classify patients in three distinct categories: *class A* is assigned to individuals with no evidence of malnutrition; *class B* to patients with moderate or indeterminate malnutrition; and *class C* to patients with definitive malnutrition. Patients in this last category typically present with recent history of unintentional weight loss and signs of tissue wasting (temporal and/or extremity most commonly). While the subjective global assessment can provide coarse information about the severity of malnutrition, it rarely yields clues pertaining to the underlying etiology (starvation vs. inflammation).

Similar methods of assessing overall nutritional status encompassing dietary history, baseline health, anthropometric and laboratory measurements have been described and used in certain patient subpopulations. These include the mini-nutritional assessment, the malnutrition universal screening tool, the instant nutritional assessment, the geriatric nutritional risk index, among others.

Anthropometric Measurements and Nutritional Indices

Anthropometric measurements have been used extensively to provide information regarding lean body mass, total fat stores, and overall nutritional health. Body composition studies aid in determining TBW, fat, and nitrogen. These anthropometric measurements can be easily performed at the bedside or an ambulatory setting, and may include an individual's height and weight (which allow calculation of the BMI), triceps skinfold, midhumeral circumference, and other body part summations. The BMI is widely used as a measure of overnutrition (a BMI of 25 to 29.9 suggests overweight status, whereas a BMI > 30 defines obesity). The BMI is calculated from an individual's height and weight using the formula:

$$\text{BMI} = \text{weight (kg)} / \text{height (m)}^2 = 703 * \text{weight (lb)} / \text{height (in)}^2$$

More advanced techniques and measurements include x-ray absorptiometry that allows a more accurate assessment of total fat and lean body mass. With the exception of the BMI, most anthropometric measurements are operator dependent, and skill and experience are important in order to obtain accurate studies.

Nutritional indices provide a means of risk-stratifying and objectively comparing individuals, as well as to guide nutritional support. The BMI is one of the most commonly utilized nutritional indices. It provides information on normal, overweight, or obese status. It also provides information on degree of protein-calorie malnutrition in underweight individuals. Other commonly used indices include the prognostic nutritional index (PNI), the nutritional risk index (NRI), and the creatinine height index (CHI).

These are calculated with the following formulas respectively:

$$\begin{aligned} \text{PNI} = & 158 - (16.6 * \text{Alb}) - (0.78 * \text{Tricep skinfold}) \\ & - (0.2 * \text{transferrin}) - (5.8 * \text{Delayed cutaneous} \\ & \text{hypersensitivity}) \end{aligned}$$

$$\text{NRI} = (15.9 * \text{Alb}) + 41.7 * (\text{actual weight [kg]} / \text{ideal weight [kg]})$$

$$\text{CHI} = (24\text{-hour urine creatine excretion}) / (\text{predicted creatine excretion based on height})$$

Serum Protein Levels. An ideal biochemical marker of malnutrition would be one that is highly sensitive and specific to nutrition intake. Although a single laboratory biomarker that could effectively describe a patient's nutritional status is lacking, numerous freely circulating serum transport proteins have been used. The most commonly utilized ones are albumin, prealbumin, transferrin, and retinol-binding protein (RBP), each with its own advantages and disadvantages. Many nutrition-unrelated parameters, most commonly inflammation, dilution secondary to large volume resuscitation, and chronic liver failure, affect the levels of these serum markers. Although it is customary for markers of inflammation, usually the C-reactive protein, to be measured with the aforementioned biomarkers (most commonly prealbumin), little data exist to support this practice.^{22,23}

Albumin. Albumin is a serum protein synthesized in the liver with a long half-life (approximately 20 days) and a relatively large total pool size. Only 5% of total body albumin is produced daily. Its main function is to carry molecules in the bloodstream and to help maintain intravascular oncotic pressure. Due to its large pool, long half-life, and relative slow turnover, it has been used as an indirect marker of protein intake, hepatic synthetic ability, and chronic nutritional status. Unfortunately, it is a negative acute-phase reactant, decreasing during the acute-phase response, and numerous nutrition-unrelated factors may affect its levels in either direction (Table 3-4). Albumin is neither a sensitive nor specific marker for malnutrition, as patients with even severe starvation can have normal levels.²⁴⁻²⁶ In critical care, hypoalbuminemia more commonly reflects illness acuity, especially during the acute phase, due to its function as a negative acute-phase reactant, its redistribution to the interstitial space, and dilution secondary to large volume resuscitation.²⁷

Prealbumin. Prealbumin, also known as transthyretin or transthyretin-bound prealbumin, similar to albumin, is a visceral protein synthesized in its majority by the liver, and to a smaller extent by the choroid plexus in the central nervous system. Its name prealbumin was originally given because it ran faster than albumin on electrophoretic gels. Its main function is to transport thyroxine (T4) and retinol (vitamin A) in the bloodstream. As a visceral protein, it is a small part of the total body protein pool, which includes serum and intracellular proteins. Consequently, it is similarly affected by many of the same factors that affect serum albumin concentrations. The main advantage of prealbumin over albumin

is its shorter half-life (2 to 3 days) which makes it more sensitive and rapidly adaptable to acute, short-lived changes in nutrient intake. Like albumin, prealbumin is also a negative-phase reactant, with values decreasing during the acute inflammatory response. Therefore, rising prealbumin levels may reflect improvement in nutritional status or resolution of the inflammatory condition. Prealbumin is commonly measured along C-reactive protein, and low levels of the former accompanied by high levels of the latter are commonly seen in inflammatory conditions, as opposed to malnutrition. While this practice is not well validated, a better use for prealbumin as a marker of overall nutritional status is to monitor trends.^{28,29}

Retinol-Binding Protein. The majority of retinol-binding protein (RBP) is present in the bloodstream in the form of retinol-circulating complex that includes prealbumin, retinol (vitamin A), and RBP. It is catabolized in the kidneys and its levels may be elevated in end-stage renal failure. RBP is dependent on vitamin A and zinc, as low levels of these conutrients inhibit mobilization of RBP in the liver.³⁰ Due to its extremely short half-life (approximately 12 hours) and typically expensive laboratory level assessment, it is rarely used as a malnutrition marker.

Transferrin. Transferrin has also been identified and used as a nutrition biomarker. It has a half-life between that of albumin and prealbumin (8 to 10 days) and fairly small total body pool size. However, because it plays a key role in iron transport, its levels are affected by iron status. Iron deficiency may lead to increased levels secondary to greater iron absorption. Under these circumstances, it may be a better marker of total iron-binding capacity, rather than malnutrition.

Nitrogen Balance

Nitrogen balance is another marker for overall nutritional status. It is an indicator of whether protein intake and catabolism are in balance, and along with trends in prealbumin levels, it is a commonly employed method to assess progress in patients on nutritional support. Nitrogen balance is calculated from the amount of nitrogen entering minus the amount leaving the human body over a 24-hour period. Nitrogen intake is estimated from total protein intake divided by 6.25 (the average nitrogen content of human protein is approximately 16%). The main route of nitrogen excretion is the urine (90% or more). Nitrogen is also lost through the skin and stool, but this loss is usually small (<2 g/day), difficult to measure, and therefore typically accounted for with a constant of 2 in the nitrogen balance equation. Total urinary nitrogen (TUN) is ideally measured, but is frequently substituted by urine urea nitrogen (UUN), because it is easier to estimate. In the latter case, an additional 2 to 3 g are typically added to the output side of the nitrogen balance equation to account for the unmeasured losses. The nitrogen balance equations are as follows:

Table 3-4 Serum Proteins Used in Nutritional Status Assessment

Marker	Reference Range	Half-Life	Elevated In	Decreased In
Albumin	3–5 g/dL	14–20 days	Dehydration, marasmus, blood transfusions, and exogenous albumin administration	Aggressive resuscitation, ascites, eclampsia, liver failure, inflammatory states, nephrotic syndrome, protein-losing states, burns, trauma/postoperative states, kwashiorkor, cancer, collagen diseases, corticosteroid use, chronic bed rest, zinc deficiency, and pregnancy
Prealbumin	18–45 mg/dL	2–3 days	End-stage renal failure, corticosteroid use, and oral contraceptives	Postoperative states, hepatitis, liver failure, inflammatory states, dialysis, hyperthyroidism, pregnancy, and severe hyperglycemia
Retinol-binding protein	4–6 mg/dL	12 hours	End-stage renal failure, diabetes, obesity, vitamin A overdose, corticosteroid use, and oral contraceptives	Postoperative states, hepatitis, liver failure, inflammatory states, and vitamin A deficiency
Transferrin	200–250 mg/dL	8–10 days	Iron deficiency, dehydration, pregnancy (third trimester), oral contraceptives, estrogens, chronic anemia, hepatitis, liver failure, hypoxia, and end-stage renal failure	Pernicious anemia, anemia of chronic disease, folate deficiency anemia, aggressive resuscitation, chronic infectious states, iron overload, acute catabolic states, uremia, nephrotic syndrome, liver failure, kwashiorkor, old age, zinc deficiency, corticosteroids, and cancer

Adapted from Parrish CR. Serum proteins as markers of nutrition: what are we treating? *Nutr Issues Gastroenterol* 2006;43(10):48–64.

$$\text{Nitrogen balance (g/day)} = \text{Protein intake}/6.25 - (\text{TUN} + 2)$$

Nitrogen balance (g/day) = Protein intake/6.25 - (UUN + 2 + 3)

A nitrogen balance of -2 to +2 g/day indicates nitrogen equilibrium, and typically represents the goal in medically indicated nutritional support. More negative balances are managed with increases in protein intake, while more positive values typically reflect anabolism in recovering patients, or simply errors in measurement in the acutely ill (a positive nitrogen balance implies anabolism, but bedridden patients with active inflammation are not anabolic). Achievement of a positive balance has been associated with improved outcomes in certain critically ill patients.³¹ Limitations of the nitrogen balance assessment include false-negative results in overfed patients; long time for the equation to re-equilibrate after adjustments in nutritional support; and renal insufficiency and upper gastrointestinal bleeding may invalidate results (due to incomplete excretion of urea nitrogen and due to excess urea nitrogen production respectively).

Indirect Calorimetry

Resting energy expenditure can be measured at the bedside with indirect calorimetry. This method, based on thermodynamic principles, calculates heat produced through the measurement of oxygen consumed and carbon dioxide exhaled. Patients must be either sedated or able to tolerate a respiration chamber placed over their heads that allows collection of exhaled air. (A less commonly utilized method is *direct calorimetry*, in which the patient is placed inside the calorimeter for measurement.) Intubated patients must have a fraction of inspired oxygen of <60%, while spontaneously breathing patients must be on room air. No air leaks (that would allow heat to escape the collection chamber) can be present. Numerous protocols have been developed to measure resting energy expenditure with as little as 5-minute testing sessions.³²

Metabolic Energy Expenditure

In most cases, energy expenditure is not measured, but estimated, on the basis that all metabolic activity occurs within the fat-free body mass. Fat-free mass is a function of body weight, height, age, and gender, and therefore, resting energy expenditure can be predicted quite reliably from these variables. In obesity, where adipose tissue becomes hypertrophic and hyperplastic, most of these relationships are preserved, but carry a weaker predictive ability. Several equations that predict basal energy expenditure, and hence daily caloric requirements, have been developed from the aforementioned variables, with the Harris-Benedict one being among the most widely used (Table 3-5).³³

Once the basal metabolic rate has been calculated, minor adjustments based on exercise frequency and intensity can be made for estimation of the daily caloric requirement for an adult to maintain current weight.³³

Table 3-5 The Harris-Benedict Equation and Adjustment Using the Harris-Benedict Principle

Men	$BMR = 88.362 + (13.397 \times \text{weight in kg}) + (4.799 \times \text{height in cm}) - (5.677 \times \text{age in years})$
Women	$BMR = 447.593 + (9.247 \times \text{weight in kg}) + (3.098 \times \text{height in cm}) - (4.330 \times \text{age in years})$
Little to no exercise	Daily kilocalories needed = $BMR \times 1.2$
Light exercise (1-3 days/week)	Daily kilocalories needed = $BMR \times 1.375$
Moderate exercise (3-5 days/week)	Daily kilocalories needed = $BMR \times 1.55$
Heavy exercise (6-7 days/week)	Daily kilocalories needed = $BMR \times 1.725$
Very heavy exercise (twice per day, extra heavy workouts)	Daily kilocalories needed = $BMR \times 1.9$

Adapted from Roza AM, Shizgal HM. The Harris Benedict equation reevaluated. *Am J Clin Nutr* 1984;40(1):168-182.

The Mifflin-St. Jeor equation appears to be even more accurate in estimating basal metabolic rate in healthy individuals³⁴:

Men	$\text{BMR} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) + 5$
Women	$\text{BMR} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) - 161$

For critically ill, or patients with highly inflammatory conditions, the estimated basal metabolic rate is adjusted upward. Not surprisingly, basal energy requirements increase significantly with an active inflammatory response, but minimally after elective surgery. The largest increases in energy expenditure are seen in patients with severe polytrauma or major burns.³⁵

Other Parameters for Nutritional Assessment

In addition to the aforementioned methods of assessment of nutritional status, many more anthropomorphic, clinical and laboratory parameters have been described. These include total lymphocyte count ($<2,000/\text{mm}^3$), CHI ($<80\%$), ideal body weight ($<90\%$), weight loss over time ($>10\%/6$ months), and skin antigen testing ($<3/4$ reactive sites over number placed). The numbers in the parentheses are suggestive of malnutrition.

OVERFEEDING AND MALNUTRITION

Overfeeding

While adequate caloric intake is necessary to maintain weight and promote health, overprovision of calories can lead to overfeeding and obesity. Excess calories, especially as carbohydrates, can lead to increased carbon dioxide production (which may prolong ventilatory weaning), hyperglycemia (which can contribute to immunosuppression and increase the risk for infectious complications), lipogenesis (indicated by a respiratory quotient >1), and hepatic steatosis (which can interfere with normal liver function). Additionally, excessive nutritional support, may lead to mineral or vitamin poisoning, and severe electrolyte imbalances, with hypophosphatemia being the most common. To avoid overfeeding, specifically in critically ill patients with numerous active medical conditions, indirect calorimetry may be indicated to accurately estimate energy expenditure during the various stages of disease.

Malnutrition

Starvation

3 During short periods of fasting, insulin levels drop and glucagon levels rise in the plasma, while glycogen is being broken down in the liver to release glucose. Liver glycogen stores are typically depleted within 24 hours of fasting. After carbohydrate stores are used up, caloric needs are met by protein and fat degradation. During starvation, down-regulated insulin results in net muscle wasting, as protein is broken down to release amino acids. These amino acids – most commonly alanine and glutamine – are used for gluconeogenesis in the liver. The resulting glucose is used primarily by the central nervous system and the hemopoietic system that rely heavily on glucose metabolism for their energy requirements. Hepatic gluconeogenesis itself also requires energy, which is typically supplied by the free fatty acid oxidation. The drop in circulating insulin levels, along with the concomitant rise in plasma glucagon, activates hormone-sensitive lipase in fatty tissue that hydrolyzes triglycerides to release free fatty acids, which in turn help generate energy for the aforementioned gluconeogenesis. Both gluconeogenesis and fatty acid oxidation require the permissive effect of cortisol and thyroxine.

During starvation, the human body attempts to recycle energy sources to the greatest extent possible. Lactate produced by the white blood cells or the muscles during anaerobic metabolism is recycled back to glucose in the liver, through the Cori cycle. BCAAs, unlike glutamine and alanine, which are taken up by the liver, are secreted by the gland, in order to provide skeletal and cardiac muscles an energy substrate. Once BCAAs are oxidized for energy, their residual amino groups are utilized to recycle alanine and glutamine, which in turn return to the liver to allow further gluconeogenesis. However efficient this conservation of energy and substrates may seem, gluconeogenesis from amino acids in the liver results in a significant loss of lean body mass, which may reach fatal levels after approximately 4 weeks. The brain adapts to prolonged starvation after about 7 to 10 days (*chronic starvation*) to use ketones derived from fat, as its primary energy source. At this stage, the basal metabolic rate decreases by as much as 30%, and all functions requiring significant amounts of energy expenditure slow down, including voluntary muscle activity and cardiac function.

Starvation versus Inflammation as the Cause of Malnutrition

Both starvation and the systemic inflammatory response result in lean body mass loss, which should indicate nutritional support.¹⁻⁴ However, the two processes have key dissimilarities that differentiate one from the other. On one hand, starvation leads to progressive loss of both lean mass and body fat, preservation of serum protein levels, and reversal of the metabolic response with feeding. The most common causes of starvation in the surgical patient are functional, and include nausea and emesis, ileus, dysphagia, and malabsorption. On the other hand, during a significant inflammatory response, the basal metabolic rate increases significantly (both anabolism and catabolism) and becomes relatively insensitive to feeding, and levels of acute-phase proteins change. Inflammation may additionally worsen malnutrition by interfering with caloric intake acutely (anorexia of acute illness) or in the chronic state (cancer cachexia). The key differences between the metabolic response to simple starvation and injury are summarized on [Table 3-6](#).

Table 3-6 Metabolic Differences Between the Response to Simple Starvation and Stress

	Simple Starvation	Stress/ Inflammation
Basal metabolic rate	–	++
Presence of mediators	–	+++
Major fuel oxidized	Fat	Mixed
Ketone body production	+++	±
Hepatic ureagenesis	+	+++
Negative nitrogen balance	+	+++
Gluconeogenesis	+	+++
Muscle proteolysis	+	+++
Hepatic protein synthesis	+	+++

METABOLIC RESPONSE TO STRESS

Neuroendocrine and Cytokine-Mediated Response to Stress

4 After injury, two distinct phases of a neurohumoral response that affect metabolism can be identified. A shorter, early “ebb” or shock phase, which typically lasts 12 to 24 hours, occurs immediately following injury. During this early phase, cardiac output, body temperature, oxygen consumption, and therefore overall metabolism are reduced. These events are often associated with blood loss and commonly lead to anaerobic metabolism and lactic acid synthesis. With restoration of the blood volume, metabolism accelerates, and is associated with increased cardiac output, altered glucose metabolism, faster tissue catabolism, and greater urinary nitrogen losses. During the “flow” phase, the basal metabolism increases to greater rates than what would be predicted on the basis of age, gender, and body size in a healthy individual. The degree of hypermetabolism is generally related to the severity of the original insult, and hence the intensity of the inflammatory response. This delayed “flow” phase response to injury is not dissimilar to what occurs following elective surgery. The response to injury, however, is usually much more intense and extends over longer periods of time.

The response to accidental injury or elective surgery, with both its phases, comprises two components: a neuroendocrine response and an inflammatory response. Catecholamines, corticosteroids, and glucagon play a principal role in the neuroendocrine response. Cytokines, complement, eicosanoids, and platelet-activating factor are key mediators of the inflammatory response. During elective surgery, the inflammatory response is typically local and confined to the surgical wound. Following a major accidental injury, extensive uncontrolled tissue damage triggers an inflammatory response and release of mediators that commonly spills over into the systemic circulation.

The hormonal response to stress appears to be the result of extensive neuroendocrine stimulation. Glucagon along with insulin resistance has potent glycogenolytic and gluconeogenic effects on the liver, which signal the hepatocytes to produce glucose from hepatic glycogen stores and gluconeogenic precursors. These gluconeogenic precursors are typically amino acids (alanine and glutamine) released from muscle. This action is facilitated by thyroid hormone. Catecholamines also stimulate hepatic glycolysis and gluconeogenesis and increase lactate production from peripheral tissues (skeletal muscle). Catecholamines additionally increase metabolic rate and stimulate lipolysis ([Fig. 3-4](#)).

The inflammatory portion of the response is arbitrated by a host of mediators, including cyto- and chemokines, complement, and eicosanoids. The initial trigger stimulates local mast cells to release numerous mediators, with pro- or anti-inflammatory properties.³⁶ The intermediaries that promote inflammation usually predominate early (tumor necrosis factor [TNF], interleukin [IL]-1, IL-6, prostaglandin-E2 [PGE2], leukotriene-4 [LT4]), whereas anti-inflammatory effectors are released later, as the body is trying to control the inflammatory response. The TNF and IL-1 stimulate IL-6 release. One of the effects of IL-6 is to reduce the level of insulin-like growth factor 1 (IGF-1), which promotes proteolysis and amino acid release from muscle. Cytokines act in concert with catecholamines, cortisol, and thyroid hormone to mobilize amino acids from skeletal muscle. As the inflammatory stimulus is controlled and eliminated, the anti-inflammatory cytokines (IL-4, IL-10, and IL-13) and eicosanoids (PGE3 and LT5) begin to predominate, and bring the inflammatory response to a conclusion. This is not to say that only pro- or anti-inflammatory mediators are being expressed, a balance between the two sets of factors favors a pro- or anti-inflammatory state at any given time, depending on the presence of ongoing stimulation.

This combined neuroendocrine- and cytokine-based response provides key nutrients to support cellular metabolism at a time when enteral nutrition typically cannot be acquired. The primary metabolic component of the acute-phase response affected by IL-6 is a qualitative alteration in hepatic protein synthesis with a resulting alteration in plasma protein composition. Characteristically, proteins acting as serum transport and binding molecules (albumin and transferrin) are reduced, and acute-phase proteins (fibrinogen and C-reactive protein) are increased. While the role of many acute-phase proteins remains unclear, many act as opsonins, antiproteases, or coagulation and wound-healing factors, with the greater aim to minimize tissue destruction associated with inflammation. For example, fibrinogen promotes thrombus formation to control bleeding, while antiproteases lessen tissue damage caused by proteases released by dying cells. C-reactive protein has scavenger function and its serum levels have been identified to be a measure of the inflammatory response.

This inflammatory response occurs at various levels. Small-scale localized inflammatory changes can be identified frequently in minor illness with no major systemic consequences, and the neuroendocrine component is only minimally, if at all, activated. In fact, these responses may be an important mechanism through which the body allows controlled exposure of the immune system to antigen. Moderate inflammation is still localized, but its effects are more obvious. Severe accidental injury or major surgery triggers a hyperactive inflammatory reaction, along with the full neuroendocrine response, the systemic effects of which are more readily identifiable (hypermetabolism, body protein catabolism, insulin resistance, fever, and acute-phase protein response). Occasionally, such an exuberant response leads to multiorgan failure, in which widespread endothelial damage, metabolic derangements, immune function collapse, and, finally, end-organ dysfunction occur.³⁷ This type of inflammation-driven illness is a major cause of death in the intensive care unit (ICU). Significant lean body mass loss is seen in survivors, however, when convalescence is under way, the inflammatory-driven metabolic changes abate, and the body can be repleted with appropriate nutritional support and exercise.

Inflammation, for reasons not fully understood, can occasionally become a chronic condition in survivors, in which impairments in metabolism typically seen in the acute phase endure, and cachexia sets in.^{38,39} This form of chronic inflammation is maladaptive and a common feature in many chronic disease states, inflammatory or not (renal, hepatic, or cardiac failure, many autoimmune diseases, cancer), and is increasingly identified in ICU survivors after prolonged and complicated ICU stays.^{38,39}

Figure 3-4. The neuroendocrine response to stress stimulates proteolysis and lipolysis, promotes gluconeogenesis and leads to glucose intolerance.

Substrate Metabolism Changes during Stress

5 During the neuroendocrine response to stress, metabolism of commonly used nutritional substrates undergoes significant changes.

Altered Carbohydrate Metabolism

Hyperglycemia occurs commonly after injury, and its intensity generally reflects the severity of the stressor. During the ebb phase, insulin levels are low and glucose production is only minimally elevated. During the flow phase, hepatic gluconeogenesis occurs at a faster pace from peripheral tissue-released precursors and hyperglycemia persists, while insulin levels are normal or elevated. This phenomenon suggests relative insulin resistance.

Altered Protein Metabolism

After major injury, nitrogen losses increase. These correlate to the extent of trauma and the injury victim's pre-existing nutritional status. In patients not receiving nutrition, protein breakdown exceeds synthesis, and negative balance results. Providing exogenous calories is important to maintain a neutral nitrogen balance.²³ Skeletal muscle is the chief source of the nitrogen lost in urine following extensive injury and it appears that amino acid release from muscle is heavily skewed toward glucogenic precursors (alanine and glutamine), even though these comprise less than 5% of muscle total protein.

In addition to skeletal muscle, the kidneys and the gastrointestinal tract also release alanine, which may be used for glucogenic purposes, even though the majority enters metabolic pathways that favor the production of urea and ammonia, to be excreted from the body.

Altered Lipid Metabolism

To support the increased metabolic rates after injury or elective surgery, triglycerides are released from adipose tissue for energy production. Glucose administration minimally affects this lipolysis, which appears to be a result of continuous neuroendocrine stimulation. Although mobilization and oxidation of free fatty acids are accelerated in injured subjects, ketone synthesis is minimal and occurs independently of protein catabolism. When severely injured patients remain unfed, their fat and protein stores become depleted rapidly, and the resultant malnutrition increases their susceptibility to infectious complications, multiple organ system failure, sepsis, and ultimately death.

Stressor-Dependent Adjustments to the Metabolic Response

Response to Elective Surgery and Accidental Injury

One of the earliest consequences of major surgery is the rise in levels of circulating cortisol in response to a sudden release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. This cortisol remains elevated for 24 to 48 hours after operation. Cortisol has generalized effects on tissue catabolism and mobilizes amino acids from skeletal muscle that provide substrates for wound healing and serve as precursors for the hepatic synthesis of acute-phase proteins or new glucose, as delineated earlier (Fig. 3-5). Associated with the activation of the adrenal cortex is stimulation of the adrenal medulla through the sympathetic nervous system, with release of epinephrine and norepinephrine. These circulating neurotransmitters play an important role not only in increasing vascular tone, which may be lessened from circulating cytokines, but also in promoting amino acid release from skeletal muscle, lipolysis in adipose tissue, and gluconeogenesis in the liver.

The neuroendocrine response to surgical trauma can also modify the various mechanisms that regulate salt and water excretion. Alterations in serum osmolarity and body fluid tonicity due to anesthesia, operative stress, and fluid resuscitation, stimulate antidiuretic hormone (ADH) and aldosterone secretion. ADH and aldosterone promote water and sodium reabsorption in the renal tubules respectively. Thus weight gain from salt and water retention is not uncommon after major surgery. Edema occurs to a varying extent in all surgical wounds secondary to local cytokine release that increases vascular permeability, and this local water accumulation is proportional to tissue trauma. This extravasated fluid eventually returns to the circulation as the postoperative inflammatory response subsides and diuresis commences, typically 2 to 3 days after surgery.

Figure 3-5. During sepsis, metabolism shifts to greater glucose synthesis and utilization, likely mirroring the greater metabolic needs of the pathogens and the mobilized host white blood cells.

Table 3-7 Differences Between Elective Surgery and Accidental Injury

Insult	Elective Surgery	Accidental Injury
Tissue damage	Minimal and controlled, usually occurring in a clean environment; tissues are dissected with care along anatomical planes and reapproximated	Can be substantial; tissues torn in contaminated field. Debridement often necessary
Hypotension	Uncommon. Pre- and intraoperative hydration employed and volume status carefully monitored intraoperatively	May occur with significant blood loss and lead to shock. Fluid resuscitation often delayed
Pain, fear, and anxiety	Typically attenuated with perioperative analgesics and anxiolytics	Generally present in the first hours after trauma
Infectious complications	Relatively rare. Procedures take place in sterile field and preoperative administration of antibiotics is commonplace	More common due to contamination and tissue devitalization
Overall stress response	Controlled and of lesser magnitude. Starvation better tolerated	Controlled and proportional to the magnitude of the injury. Malnutrition poorly tolerated

Glucagon from the endocrine pancreas is also released at greater rates postoperatively, while insulin levels decrease. This response appears to be associated with the increased sympathetic activity that typically follows surgical trauma. The rise in glucagon and the corresponding fall in insulin act as potent signals accelerating hepatic glucose synthesis.

This postoperative catabolic period, which may be worsened by inadequate caloric intake, has been termed the “adrenergic–corticoid phase,” which generally lasts 1 to 3 days and is followed by the “adrenergic–corticoid withdrawal phase,” which may last an additional 1 to 3 days. An anabolic phase ensues, which can occur at a variable time during a surgical patient’s convalescence. In general, in the absence of significant postoperative complications, this stage starts 3 to 6 days after major abdominal surgery, usually when the bowel function returns and an oral diet is initiated. This phase is characterized by positive nitrogen balance and weight gain. Protein is synthesized at an increased rate, and return of lean body mass and muscular strength ensues.

Whether the body is injured within the carefully monitored confines of the operating room or accidentally, the response to tissue trauma is similar, although key differences exist. In accidental injury, tissue damage is uncontrolled and happens in a contaminated environment. The associated volume loss can be substantial and life-threatening. Pain and the sympathetic nervous system overexcitation are heightened and uncontrolled. As a consequence, the magnitude of the physiologic response to major accidental injury is considerable. In contrast, the elective tissue trauma inflicted occurs in a planned and monitored setting, and the team caring after the surgical patient perioperatively ensures appropriate resuscitation designed to attenuate such changes. Hydration during and after surgery is common, and the latter typically happens in a clean field. At the same time, the anesthesiologist provides medications to minimize anxiety and fear, to minimize the sympathetic nervous system response. Appropriately selected pharmacologic agents are used to minimize undesirable cardiovascular responses, and analgesic techniques are employed to minimize postoperative pain. As a result, the physiologic responses to elective surgery are generally of lesser magnitude than those following major accidental injury and are typically tolerated better (Table 3-7).

Metabolic Adaptations to Sepsis

The metabolic changes following invasive infection are not dissimilar to those seen after elective surgery and accidental trauma, although they are typically less predictable. Severe infection is characterized by fever, hypermetabolism, diminished protein economy, altered glucose dynamics, and accelerated lipolysis, much like the injured patient. Anorexia that commonly follows systemic infection is an added factor contributing to the loss of lean body mass.

Hypermetabolism and increased oxygen consumption are additional traits, with the latter reaching peak levels that may be 50% to 60% higher compared to baseline in severe sepsis. A portion of this metabolic acceleration can be attributed to the escalation in enzymatic reaction rates associated with fever. It is estimated that the base metabolic rate rises by 10% to 13% for every 1°C rise in central temperature. Glucose metabolism is increased to much greater levels in systemically infected subjects, compared to trauma victims. As an example, burn patients synthesize glucose at a rate approximately 50% above normal. If superinfection ensues, hepatic glucose production doubles, and it appears that the additional glucose requirements correlate with the bacterial burden and white blood cell activation (Fig. 3-5).

Increased proteolysis and nitrogen excretion leading to negative nitrogen balance typically occur

following invasive infection, in a pattern that is similar to that described for injury. Visceral amino acid uptake is accelerated during sepsis, and this is matched by faster amino acid efflux from skeletal muscle. In infected burn patients, splanchnic amino acid uptake is amplified over 50% above rates in uninfected burn victims with comparable injuries. These amino acids serve either as glucose precursors, or building blocks for acute-phase protein synthesis.

Fat is another major fuel utilized for energy in infected patients. Increased fat catabolism is particularly profound in patients during periods of inadequate nutritional support or relative starvation. Lipolysis is accelerated among other reasons by a heightened sympathetic activity, and serum triglyceride levels reflect the balance between synthesis in the liver and storage in the peripheral adipose tissue. Marked hypertriglyceridemia has been associated with certain gram-negative infections, but frequently triglyceride concentrations are normal or low, indicating enhanced utilization and clearance by other organs. Infected patients cannot convert fatty acids to ketones as efficiently in the liver, and do not adapt to starvation as well as their fasted, unstressed counterparts. It is postulated that the low ketone state of infection is a consequence of the hyperinsulinemia, which in turn follows insulin resistance in high-degree catabolic states.

Trace elements and electrolytes (zinc, iron, potassium, magnesium, and inorganic phosphate) typically follow alterations in nitrogen balance. Although the iron-binding capacity of transferrin typically remains unchanged in early infection, free iron cannot be found in the plasma of patients with severe pyrogenic infections. Similar changes are seen in zinc levels. These decreases cannot be totally accounted for by total body losses, rather an accumulation of these elements appears to occur in the liver, through not yet elucidated mechanisms. Unlike iron and zinc, serum copper levels generally rise, seemingly due to greater ceruloplasmin synthesis in the liver.

Metabolic Response to Cancer and Acquired Immunodeficiency Syndrome

Patients with cancer and acquired immunodeficiency syndrome (AIDS) have similar metabolic states, characterized by chronic malnutrition, typically a result of anorexia and treatment side effects, and prolonged low-grade inflammatory changes. Cancers of the aerodigestive tract interfere with taste, swallowing and/or digestion, precluding adequate caloric and/or protein intake. Supplementation with zinc and B vitamins may help taste-related symptoms, and soft mechanical diets may allow greater caloric intake in patients with swallowing difficulties or proximal gastrointestinal tract malignancies. The aggressive management of nausea and vomiting, may also afford greater interest in food.

Cancer- and AIDS-related cachexia is seen in the later stages of disseminated disease and represents a chronic catabolic state due to unrelenting inflammation that is difficult to reverse, even with adequate caloric and protein supplementation. Proinflammatory cytokines (TNF, IL-1, and IL-6) are constantly released in response to the tumor or an infectious source in AIDS, respectively, and lead to a chronic state of muscle wasting and fat loss. The cachexia of cancer and AIDS is difficult to manage, as removing the inflammatory stimulus can prove elusive. However, mitigation of the chronic, low-grade inflammatory response may be useful, and so can aggressive nutritional supplementation and appetite stimulants.⁴⁰

Another practice that is becoming increasingly popular is the repurposing of the dietary balance of n-6 to n-3 fatty acids. Thirty eight fatty acids from the diet eventually become incorporated into cells' plasma membranes, influencing their function and characteristics, and act as precursors for eicosanoid synthesis.³⁹ The eicosanoids produced depend on the type of fatty acids found in plasma membranes. The n-6 fatty acid linoleic acid is converted to arachidonic acid, which in turn gives rise to proinflammatory eicosanoids PG2 and LT4. The n-3 fatty acid linolenic, eicosapentaenoic, and docosahexaenoic acids yield more anti-inflammatory PG3 and LT5. These eicosanoids interrupt the release of IL-6, thus potentially allowing IGF-1 levels to normalize in cachectic patients.⁴⁰ While a typical Western diet is high in n-6 to n-3 fatty acids ratio (~15:1), more therapeutic ratios of 2:1 to 4:1 can be targeted, in addition to maximizing protein and caloric intake. Such efforts have been met with improving clinical outcomes in patients with pancreatic cancer⁴¹ or generalized malignancies.⁴²

Stimulants of the Stress Response

Hypovolemia and End-Organ Hypoperfusion

Following hemorrhage, pressure receptors in the aortic arch and carotid, and volume (stretch) receptors in the left atrial wall detect the acute drop in circulating blood volume and pressure and respond by signaling the central nervous system. Activation of the sympathoadrenergic axis leads to a rise in stroke volume to maintain a perfusing pressure, at the expense of tachycardia. ADH and aldosterone are also

released, in an attempt to restore circulating plasma volume. ADH is released by the posterior pituitary in response to hypotonicity and increases water reabsorption in the renal tubular apparatus. Aldosterone is produced through activation of the renin–angiotensin system, when the renal juxtaglomerular apparatus senses a drop in the renal perfusion pressure, and also increases reabsorption of sodium and water. These mechanisms are only partly effective and, if bleeding is not controlled surgically and resuscitation inadequate, peripheral tissue oxygenation does not suffice to meet metabolic demands and metabolism switches to anaerobic metabolism, leading to lactate production and lactic acidosis.

Tissue Damage

Tissue damage appears to be one of the principal factors that can set the stress response into motion. Hypovolemia itself is rarely an adequate stimulus to trigger a hypermetabolic response, unless associated with extensive tissue damage or infection. However, if hypoperfusion is prolonged, cellular death may ensue, which in turn will lead to release of toxic products that can initiate the “stress” response.

Pain

Pain can be an important activator of the sympathoadrenergic response and lead to a catecholamine surge with the metabolic effects described earlier. Local tissue destruction is sensed as pain centrally, which triggers numerous efferent pathways preparing the body for what is termed the “fight or flight” response.

Determinants of the Host Response to Stress

Each individual, depending on their genetic traits and certain environmental parameters may respond differently to similar tissue injury patterns. The idiosyncratic nature, intensity, and duration of the stress response may vary extensively in numerous ways in individuals with certain similar genetic and body composition characteristics.

Body Composition

Body composition is a major determinant of the metabolic response seen in the acute phase after surgical or accidental trauma. Posttraumatic nitrogen excretion is directly proportional to the size of the lean body mass. The balance between nitrogen intake and output is a useful marker of protein metabolism. A greater muscle mass due to greater long-term physical activity may also confer an advantage during acute surgical illness and starvation, as the ability of the lean body mass to provide amino acids for gluconeogenesis during acute illness when it is needed the most, is optimal. Conversely, excessive adiposity may affect outcomes after intense stress, and this is likely due to an abundance of proinflammatory precursors.⁴³

Baseline Nutritional Status

A strong relationship exists between preoperative protein depletion and postoperative complications.⁴ Protein-depleted patients have lower pulmonary muscle strength and reserve, and are more susceptible to infectious complications, including of the respiratory tract, as well as of the surgical site. Patients with poorer baseline nutrition also experience impaired wound healing and are subject to longer postoperative hospital stays.

Age and Gender

Certain patterns in the metabolic response to surgical pathology that occur with aging can be attributed to alterations in body composition. Although weight remains roughly stable, fat mass tends to increase with age, while lean body mass tends to decline. The loss of strength that accompanies immobility, starvation, and acute surgical illness may have significant consequences. Although the increased energy requirements after elective surgery occur essentially independent of age, the capacity of muscle to serve as a source of amino acids may be limited during acute surgical illness in the elderly, and muscle strength may rapidly become inadequate for respiratory function.

In addition to a smaller muscle mass, older age is commonly associated with a greater prevalence of cardiovascular and pulmonary disease. Relatively decreased arterial compliance, lower baroreceptor sensitivity, and a blunted response to the catecholamine surge may impair the cardiovascular homeostatic response during acute surgical illness. Thus, tissue oxygenation may not be able to meet the heightened demand.

Gender, in addition to age, may affect the body’s ability to adapt to surgical stress. Observed

differences in the metabolic response between men and women in general reflect differences in body composition. Lean body mass, as a proportion of total body weight, is lower in women than in men. This difference is thought to account for the lower net loss of nitrogen after major elective abdominal surgery in women. Women in general, have approximately half the skeletal muscle mass of men of the same age. Therefore, young muscular men experience the greatest nitrogen losses during acute surgical illness, as opposed to elderly, sedentary women.⁸

NUTRITIONAL SUPPORT

Nutritional Support in Elective Surgery

Most patients undergoing elective operations are adequately nourished, and are typically only fasted the evening before surgery. Unless the patient has suffered significant preoperative malnutrition (subjective global assessment class C) or has a major intraoperative or postoperative complication, intravenous solutions containing 5% dextrose may be administered for up to 5 to 7 days with no detrimental effect on clinical outcomes. In patients who present with the evidence of starvation-related malnutrition, preoperative addition of balanced macronutrient, and high-protein supplementation could be useful. This preoperative support should be initiated as far in advance as possible, even though it is estimated that the minimum time required to derive any benefit from this support is in the range of 2 to 4 weeks.⁴⁴ During this period, electrolyte abnormalities should be addressed, and early involvement of a nutritionist would be advisable.

Bowel function typically returns within the first 5 to 7 postoperative days in the majority of surgical patients, and an oral diet or enteral feedings can be resumed. The increased cost of feedings and the potential complications associated with parenteral nutrition cannot be justified. Conversely, in patients who are malnourished preoperatively or prolonged postoperative ileus has rendered them unable to be fed enterally for more than 5 to 7 days, nutritional support should be considered. The nutritional status should be assessed early, so this piece of information can be integrated into decision-making and nutrition care planning. Enteral feedings are superior and always preferred to parenteral nutrition in patients who can tolerate an enteral diet. Standard high-protein feeding formulas are adequate. The choice of product and volume of feeding are based on the results of the nutrition assessment. The majority of tube feeding formulas today are rich in water-soluble dietary fiber, which is considered standard in the nutritional care of the surgical patient. Specific adjustments can be undertaken, if special considerations (e.g., cardiac failure, renal failure, diabetes, etc.) have to be made. Preoperative addition of a balanced macronutrient high-protein supplement is useful to initiate as far in advance of surgery as possible, although in this severely malnourished population, the time needed to see benefit from supplementation is unknown (estimated minimum of 2 to 4 weeks).

6 One of the best studies to date evaluating the efficacy of preoperative TPN was published by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group.⁴ Over 3,000 patients requiring mostly elective gastrointestinal procedures were randomized to receive parenteral nutritional support for at least 7 days preoperatively versus none, if they were deemed to be malnourished preoperatively. Patients with severe malnutrition ($>15\%$ weight loss and serum albumin <2.9 mg/dL) preoperatively had fewer noninfectious complications (impaired wound healing), if they were provided TPN before surgery, however, infectious complications (pneumonia, surgical site infections, and line infections) were more common in the TPN group. This study strongly suggests that preoperative TPN should be considered only to severely malnourished patients who cannot be fed via the enteral route.

Numerous studies that have followed have reached similar conclusions, and have led the SCCM and ASPEN to recommend targeted preoperative nutritional support for those deemed malnourished. This support should ideally be oral, enteral, or in rare circumstances parenteral and with therapeutic intent.⁶ In fact, while initial guidelines advocated the use of artificial nutrition if preoperative weight loss $>10\%$ has occurred or oral intake is not deemed achievable for more than 7 days postoperatively, interest in supporting all surgical patients perioperatively has been on the rise, regardless of baseline nutritional status.⁴⁵

Nutritional Support in Critical Care

7 While resuscitation, bleeding control and preservation of the vital body functions, such as maintenance of gas exchange and supporting of adequate cardiac output, remain immediate priorities for survival in any critically ill surgical patient, it is increasingly recognized that nutritional support is

an integral part of the metabolic care of the critically ill, and aggressive pursuit of target energy requirements is associated with optimal wound healing, recovery, and rehabilitation. Critically ill patients commonly have anorexia that can be adaptive or maladaptive and may be unable to be fed by mouth volitionally for periods, which can range from days to months, and severe malnutrition can complicate their course and adversely affect outcomes, unless they are provided with enteral or parenteral nutrition.⁴⁶ Several studies have underlined the association between energy deficit in critical illness and longer ICU stays, greater incidence of infectious complications, and even mortality.^{47–50} The finding that enteral nutrients exert a trophic effect on the cellular integrity and function of the gut mucosa has provided the rationale for initiating enteral feedings early in the course of critical illness. In fact, evidence from observational studies appears to support that critically ill patients who were fed earlier had better overall outcomes compared to those that did not,⁵¹ and these improved outcomes have led critical care nutrition to be at the forefront of ongoing research worldwide. Therefore, regardless of baseline nutritional status, any critically ill patient who is not expected to resume an oral diet within 3 to 4 days should have nutritional support instituted as soon as technically and logistically feasible, ideally within 24 to 48 hours after admission, and have their blood glucose levels maintained <140 mg/dL.⁵² Patients on enteral nutrition, should have their head of bed elevated at 45 degrees, or be in steep reverse Trendelenburg position if spinal precautions preclude this measure, to minimize aspiration risk.^{18,20}

The optimal method of estimating daily energy requirements in the critically ill remains a subject of debate. It would be ideal if energy requirements were calculated precisely on a daily basis using indirect calorimetry, as this method appears to lead to greater energy provision than less precisely calculated energy targets, even though this practice was associated with a greater incidence of infectious complications and a longer overall ICU length of stay.⁵³ Indirect calorimetry, however precise, can be impractical, if not even impossible to apply in certain critically ill individuals.⁵⁴ Additional challenges facing critical care nutrition include the frequent interruptions in nutrition delivery for a variety of reasons, including delayed gastric emptying and transfers outside the ICU for diagnostic or therapeutic procedures. When protocols to aggressively advance nutrition are in place, it appears that critically ill patients are able to achieve their caloric goals earlier, even though these practices may not necessarily translate to better overall outcomes.^{55–57} With regard to delayed gastric emptying, which is commonly cited as a reason for slow advancement of enteral feedings, it appears that advancing tube feedings without measuring or accepting residual volumes as high as 500 cc/4 hours results in quicker attainment of the caloric goals, with no concomitant rise in the incidence of nutrition-related adverse events.⁵⁸ The use of prokinetic agents (erythromycin may be more effective than metoclopramide), as well as postpyloric feeding delivery has also been advocated to minimize the issue of delayed gastric emptying, however, other than achievement of nutritional goals being slightly earlier in the course of critical illness, no definitive improvement in outcomes has been demonstrated.^{59–62} There is some divergence on whether immune- or inflammation-modulating feeding formulas are indicated in some critically ill patients. There is at least one quality study that has been published since the guidelines that support the use of such feedings in patients with sepsis and risk for acute respiratory distress syndrome or acute lung injury.⁶³

Access Routes for Nutrition

Enteral or Parenteral

8 An issue with reliance solely on enteral nutrition is that attaining caloric targets may prove elusive, due to a partly functional gastrointestinal tract or side effects associated with enteral feedings. While enteral feedings are always preferable to parenteral nutrition in general, the timing of initiation of TPN in patients unable to tolerate or with contraindications for enteral feedings remains controversial. European guidelines recommend early initiation of TPN to minimize nutritional deficits, while North American guidelines favor hypocaloric enteral nutrition for up to 1 week in patients with good nutritional baseline before considering TPN.^{48,49} The rationale on the delay in TPN administration is based on complications associated with the use of TPN, such as infections, hyperglycemia, hypertriglyceridemia, and liver function abnormalities.^{64–67} The latter seems to be supported by more recent high-quality data that demonstrate that patients receiving partial enteral nutrition demonstrate a lower incidence of ICU-acquired weakness, spend less time in the ICU and the hospital, and require shorter length of vital-organ support, and incur less costs, compared to their counterparts in whom partial enteral nutrition was supplemented with TPN.^{68–71} However, conflicting data exist on the effect of nutritional supplementation with TPN on infectious outcomes in patients receiving hypocaloric

enteral feedings from more recent trials.^{68,69,72} In critically ill patients with a relative contraindication (e.g., gastric residual volumes >500 mL or postoperative ileus) for early enteral nutrition, it appears that early TPN helps decrease total length of stay on mechanical ventilation.⁷³ Whether early parenteral nutrition is beneficial in patients with an absolute or prolonged contraindication for enterally administered nutrition remains a topic of debate, even though it is fairly well established that the greater incidence of infectious complications may outweigh the benefits of early achievement of nutritional goals in patients in their first 5 to 7 days in the ICU.^{68,74}

Total Parenteral Nutrition Considerations

As the term implies, and due to the high osmolarity of its content, TPN must be delivered centrally to minimize the risk of venous sclerosis. Patients on TPN therapy should be monitored regularly by measuring blood sugar, serum electrolytes, and liver function tests, as abnormalities in these laboratories are common. TPN-related complications can be broadly categorized into those that are access related, metabolic, and infectious. A list of these is summarized on [Table 3-8](#).

Table 3-8 TPN-Related Complications

Complication	Etiology
Access Related	
Pneumothorax	Air accumulation between the pleural leaflets from puncture/laceration
Carotid/subclavian arterial injury	Accidental puncture of the adjacent arterial structure
Catheter malposition and arrhythmias	Tip of catheter may find its way into an unintended venous structure or the right atrium causing arrhythmogenesis
Venous thrombosis	Thrombus formation in a major vein, due to alterations in blood flow and presence of a foreign body
Metabolic	
Hyperglycemia	Excessive carbohydrate administration, glucose intolerance, or combination of the two
Hypoglycemia	Sudden cessation of TPN, while insulin stimulation has not subsided
CO ₂ retention	Carbohydrate calories in excess of energy requirements
Azotemia	Excessive protein administration with inadequate calories
Essential fatty acid deficiency	Inadequate essential fatty acid administration
Hypertriglyceridemia	Rapid fat infusion or decreased fat clearance
Hypophosphatemia and hypokalemia	Sudden full-strength nutritional restitution in a starved patient (refeeding syndrome)
Any electrolyte abnormality	Excess or inadequate electrolyte supplementation
Hemorrhagic diathesis	Vitamin K deficiency
Infectious	
Septicemia	Catheter tip becomes colonized with bacteria and continuously seeds bloodstream
Skin site cellulitis	Skin flora enters the subdermal/subcutaneous space
Pneumonia, other systemic infectious	High n-6 fatty acid content adversely affects immune function

9 Hyperglycemia is common in surgical patients, especially during high-stress periods, or they were relatively glucose intolerant or frankly diabetic at baseline. This side effect of TPN can generally be controlled with subcutaneous or intravenous insulin administration if mild or moderate–severe respectively, and eventually by adding insulin to the TPN formulation, once the daily insulin requirements have been calculated. It has been shown that stressed individuals can maximally oxidize up to 4 to 5 mg of glucose/kg/min. For a 70-kg man, this is equal to approximately 400 to 500 g/day (1,600 to 2,000 kcal/day). Therefore it is common for patients to receive up to two-thirds of their daily caloric needs in carbohydrate form through TPN. Excess glucose can result in hyperglycemia and glycosuria, can be converted to fat, and deposited in the liver. Glycosuria with its osmotic load can lead to osmotic diuresis, which can be misinterpreted as a sign of adequate resuscitation status or transition to recovery phase, while the patient may actually be clinically worsening.

Fat is an important fuel for the critically ill, as stressed patients preferentially utilize endogenous fat as an energy source. Fat oxidation is only minimally affected by carbohydrate administration during stress, unlike traditional starvation, and glucose infusion above certain levels may lead to hepatic steatosis. Lipids are commonly added to TPN formulations to help meet the caloric requirements, as well as to provide the essential fatty acids and to minimize complications associated with the infusion of large amounts of carbohydrate-containing fluids. Lipid emulsions for TPN solutions are mostly vegetable fat based, and contain primarily long-chain fatty acids. Inclusion of lipids in the TPN provides the essential linoleic acid, inhibits lipogenesis from carbohydrates, and helps lower the respiratory quotient

(RQ), which may benefit patients with carbon dioxide retention. However, formulations with a high n-6 polyunsaturated fatty acid content (linoleic acid in particular) may attenuate acute lung injury,⁷⁵ and by affecting plasma membrane fluidity, the ability to phagocytose bacteria may be impaired. Newer nutritional methods of modifying the catabolic response to injury and infection propose the use of n-3 fatty acids, which may decrease eicosanoid synthesis and thereby diminishing the vasoconstriction, platelet aggregation, and immunosuppression that may occur when n-6 derivatives are given. Studies suggest that n-3 fatty acids may be of benefit to the critically ill patient.⁷⁶

The amounts of the various electrolytes provided to patients receiving TPN vary, depending on previous volume status and preexisting electrolyte abnormalities. Careful monitoring of serum electrolyte levels is critical, especially during the acute phase of disease or in severely malnourished individuals, because as metabolism switches to the anabolic phase, potassium and phosphate can move rapidly into the intracellular compartment, leading to potentially fatal hypokalemia or hypophosphatemia, in what is known as the refeeding syndrome.⁷⁷ Vitamin and trace mineral levels, although not as life-threatening, should also be occasionally monitored. The composition of a standard TPN solution is shown in [Table 3-9](#).

A significant downside of TPN is that the gastrointestinal tract goes into misuse, and evidence suggests that this may exacerbate intestinal microflora translocation from the gut lumen to the mesenteric lymph circulation, worsening total bacterial load and stress during an already compounded clinical situation. Clinical evidence suggests that TPN, under certain circumstances, may accentuate stress, and predispose to gut-derived infectious complications, and even multiple organ failure,^{78,79} while compared to enteral nutrition, it may minimize episodes of hypoglycemia and vomiting.⁸⁰

Enteral Nutrition Considerations

10 11 Enteral nutrition is safer and less expensive than parenteral nutrition, and numerous studies have demonstrated the superiority of enteral nutrition compared to parenteral, in decreasing postoperative infectious complications and increasing collagen deposition at anastomotic sites, improving wound tensile strength.⁸¹ The gastrointestinal tract can be used for administration of complex nutrients that cannot be provided as readily intravenously, such as polypeptides and fiber. Gut processing of many of these nutrients stimulates hepatic protein synthesis, while intravenous administration bypasses the portal circulation altogether. In addition to the systemic benefits of enteral nutrition, enteral feedings afford significant local benefits on the gut mucosa itself. Enterocytes are being fed directly, and the absorptive surface of the mucosa is stimulated and maintained. Luminal nutrients, such as glutamine and short-chain fatty acids, are used as fuel by small bowel enterocytes and colonocytes respectively.⁸² The trophic effects of luminal nutrition are well documented, even if small amounts of enteral feedings are provided, and a growing body of evidence suggests that earlier enteral nutrition is preferable.^{83–85} An additional immunologic benefit of enteral nutrition is that complex polypeptides and long-chain fatty acids stimulate the production of gut-derived immunoglobulin A, which is important in reducing bacterial translocation. Luminal nutrients also help maintain a normal pH and flora, thus diminishing the risk of opportunistic bacterial overgrowth in the bowel. In addition to the physiologic, metabolic, and immunologic benefits of enteral nutrition, safety and cost benefits also exist. Enteral feedings are considered safer than parenteral nutrition. The latter places patients at a greater risk for hyperglycemic events, which may partly inhibit neutrophil-mediated immune function, and may be the reason why TPN-nourished patients may be at a greater risk for infectious complications, even though this risk may be eliminated with tight glucose control.⁸⁰ Finally, there are obvious cost benefits, as tube feedings are in general cheaper than parenteral nutrition formulations.

Table 3-9 Composition of a Standard Total Parenteral Nutrition Formulation

Volume	10% Amino acid solution 50% Dextrose solution Fat emulsion Electrolytes + vitamins + minerals Total volume	500 mL 500 mL — ~50 mL ~1,050 mL
Composition	Amino acids Dextrose Total N Dextrose kcal mOsm/L	50 g 250 g $50/6.25 = 8$ g $250 \text{ g} \times 3.4 \text{ kcal/g} = 840 \text{ kcal}$ ~2,000
Electrolytes to Total Parenteral Nutrition Solutions		
	Usual Concentration	Range of Concentrations
Sodium (mEq/L)	60	0–150
Potassium (mEq/L)	40	0–80
Acetate (mEq/L)	50	50–150
Chloride (mEq/L)	50	0–150
Phosphate (mEq/L)	15	0–30
Calcium (mEq/L) ^a	4.5	0–20
Magnesium (mEq/L)	5	5–15

^aGenerally added as calcium gluconate or calcium chloride: one ampule of calcium gluconate = 1 g of calcium = 4.5 mEq.

Although enteral nutrition is the preferred method for nutritional support in malnourished patients, or subjects at risk for developing malnutrition and have an intact gastrointestinal tract, a problem surgical patients are commonly facing is intestinal inactivity, especially after gastrointestinal procedures. Postoperative ileus is frequent, reflects functional immobility of the gastrointestinal tract, and is typically proportional to the amount of manipulation the bowel sustained during the surgical intervention. Patients who are either unable to meet their daily caloric and nutrient needs are candidates for enteral support. Factors that can help determine the timing of initiation of enteral nutrition include preexisting malnutrition, current illness acuity and duration, estimated catabolic activity, and anticipated return to per os intake. Contraindications to enteral feedings are usually relative or temporary, and include short, obstructed, or perforated bowel, a gastrointestinal tract in discontinuity, protracted vomiting, fistulas, or active gastrointestinal ischemia. While gastrointestinal bleeding or worsening hemodynamic instability has been traditionally quoted as additional contraindications, it appears that enteral nutrition can be safely administered during these.^{86–88}

Despite the numerous benefits of enteral nutrition, it is not completely free of complications. These can be categorized in access related, functional, and metabolic, and are summarized in [Table 3-10](#). In general, these can be avoided with meticulous care while inserting and maintaining feeding tubes, considering using nasal bridles,⁸⁹ ensuring head of bed elevation to minimize risk of aspiration, using motility agents when gastric motility is suboptimal, closely monitoring patients' metabolic profile and adjusting content, or adding bulking agents if osmotic diarrhea develops.

Enteral feedings are generally categorized into *intact or polymeric* (protein, carbohydrate, and lipid molecules exist in an unaltered form – usually given to patients without absorption or digestion difficulties), *hydrolyzed or monomeric* (contain predigested proteins, simple sugars, and medium-chain triglycerides – are a good option for patients with impaired digestive capacity), and *modular* (typically contain one type of fuel, carbohydrate, lipids or fat, and can be combined to address each patient's specific needs). Some of the most commonly used enteric feeding formulas and their metabolic characteristics are shown on [Table 3-11](#).

Table 3-10 Enteral Nutrition-Related Complications

Complication	Etiology
Access Related	
Feeding tube malposition, clogging, and accidental removal	The feeding tube can be misplaced in the tracheo-bronchial tree, it can become clogged with dense tube feedings or inadequately crushed medications, or be accidentally removed
Oro/naso-, gastric or -enteral tube perforation of the proximal gastrointestinal tract or tracheobronchial tree	Accidental puncture of the wall of the structure the feeding tube is placed into
Pressure ulcers at skin entry site and sinusitis	A foreign body is continuously pressing against healthy skin, and increases risk of bacterial colonization of the nasal passages
Functional	
Nausea, vomiting, and abdominal distention	Usually due to delayed gastric emptying
Diarrhea	Usually polyfactorial, but high-protein content and high osmolality of enteral feedings are the most common culprits
Metabolic	
Electrolyte abnormalities	When enteral nutrition content is inadequate to cover daily needs. Hyperosmolality may be a consequence when calorically dense enteral feedings are administered
Volume overload	From excess sodium and water loading, typically in patients with preexisting heart failure
Hyperglycemia	Less common than in patients receiving TPN, but may manifest in patients with diabetes or impaired glucose tolerance, or can herald sepsis

Table 3-11 Commonly Used Enteral Nutrition Formulations

Product Name	Calories (per mL)	Protein (g/L)	Carbohydrates (g/L)	Fat (g/L)	Fiber (g/L)	Osmolality (mOsm/L)	Special Features
Tube Feeding Formulations							
Osmolite 1 Cal	1.06	44	144	35	0	300	Isotonic
Jevity 1.2 Cal	1.2	56	169	39	18	450	High protein with fiber
Jevity 1.5 Cal	1.5	64	50	50	22	525	Concentrated calories with fiber
Promote with Fiber	1	63	138	28	14	380	Very high protein with fiber
Nepro with Carb Steady	1.8	81	161	96	13	745	Renal formula
TwoCal HN	2	84	219	91	5	725	Calorie and protein dense
Vital AF 1.2 Cal	1.2	75	111	54	5	425	Peptide-based elemental with high protein
Vital high protein	1	88	112	23	0	353	Peptide-based elemental with high protein
Pivot 1.5 Cal	1.5	94	172	51	7.5	595	Immune support
Vivonex RTF	1	50	176	12	0	630	Elemental (amino acids)
Oral Supplements*							
Product Name	Calories	Protein (g)	Carbohydrates (g)	Fat (g)	Fiber (g)	% Water	Special Features
Ensure Plus (per 8 fl)	350	13	51	11	3	76	High calorie and high protein
Glucerna Shake (per 8 fl)	220	10	26	9	3	84	Diabetic formula
Ensure Clear (per 6.8 fl)	200	7	43	0	0	84	Clear liquid
Juven (per 24 g)	80	14 (amino acids)	8	0	0	n/a	Helps build lean body mass to support healing
Pro-Stat Sugar free (per 30 mL)	100	15	10	0	0	n/a	Protein
Nutrisource fiber (per 4 g)	15	0	4	0	3	n/a	Fiber

*Per amount noted in product name column.

Macro- and Micronutrient Selection

An additional topic of debate is whether selection of specific macro- and micronutrients to be included in nutritional formulas, be it enteral or parenteral, can afford specific benefits to patients receiving them, depending on the underlying pathology. Gluconeogenesis from amino acids (glutamine and alanine) released from muscle protein breakdown cannot be fully suppressed with exogenous glucose and insulin administration, due to the complex hormonal stress response the human body elicits during critical illness, which results in relative insulin resistance. It was postulated, therefore, that exogenous amino acid and oligopeptide infusion would help minimize lean body mass erosion. However, even though the total nitrogen equilibrium appears to be shifted toward a more positive balance when this practice is employed, it does not translate to better outcomes.⁹⁰ Therefore, the optimal protein to total energy ratio in critical illness remains largely unknown.

12 Glutamine is the most abundant nonessential amino acid and in humans it is predominantly released with skeletal muscle proteolysis. It is one of the key precursors for hepatic gluconeogenesis at times of stress, and low glutamine levels have been associated with poor outcomes in critical illness, as it is an important nutrient necessary for the function of immune cells, enterocytes, and hepatocytes. It has been postulated that low glutamine levels are a consequence of muscle wasting, and a meta-analysis of early randomized controlled trials suggested that glutamine supplementation may help decrease infectious complications, hospital length of stay, and even mortality.⁹¹ However, this finding has not been replicated in newer, higher-quality studies, and in fact, it appears that aggressive glutamine supplementation may increase risk of death in patients with organ failure.⁹²⁻⁹⁴ These findings do not support glutamine supplementation routinely. Its supplementation may be beneficial when depletion is severe or when the intestinal mucosa is damaged by chemo- and/or radiation therapy.⁹⁵ Similarly, arginine supplementation may be associated with a lower infectious risk and shorter hospital length of stay, however, no currently available evidence support its use during critical illness.⁹⁶

The n-3 fatty acids (present in fish oil preparations) have been shown to have anti-inflammatory effects, while n-9 fatty acids (present in olive oil) have a neutral effect on inflammation, and n-6 fatty acids (in soybean oil) appear to be proinflammatory.⁹⁷ On the basis of low levels of n-3 fatty acids in acute lung injury patients and the proinflammatory properties of n-6 fatty acids, the lipid profile of such patients was hypothesized to contribute to worsening acute lung injury, and some initial studies suggested that administration of high n-3 to n-6 fatty acid ratio formulas may benefit critically ill patients.^{98,99} However, more recent, higher-quality studies have failed to show a beneficial effect of rich in n-3 fatty acid preparations in either enteral or parenteral nutrition formulations.^{100,101} Currently, the lack of high-quality evidence precludes any recommendation on the use of specific lipids in critically ill patients.

13 Micronutrients, as electrolytes, vitamins and trace elements are generally termed, are administered in critical illness to prevent deficiencies and associated complications. With repletion of micronutrient stores after starvation, refeeding syndrome can occur, which typically unmasks severe deficiencies in potassium, phosphate, and thiamine. This can be life-threatening and present with lactic acidosis, cardiac arrhythmias, worsening respiratory failure, and even heart failure. Therefore, routine administration of micronutrients during critical illness is commonly warranted. Provision of therapeutic doses of trace elements (selenium, copper, zinc, and iron) and vitamins (E, C, and beta-carotene) with antioxidant activity has also been proposed,¹⁰² however, recent randomized controlled data failed to demonstrate a benefit.⁹³ Selenium supplementation may also be beneficial in subjects with selenium deficiency, and the potential benefit is supported by a recent meta-analysis.¹⁰³

Current recommendations for nutritional support during critical illness are summarized on [Table 3-12](#).

Access Routes

TPN solutions are administered through a central venous catheter, generally inserted in the subclavian or internal jugular vein, or through peripherally inserted central catheters (PICCs) that are typically inserted in veins of the antecubital fossa and have their ends reach the atriocaval junction. Administration of TPN through femoral venous catheters is avoided as possible, due to the greater incidence of infectious complications this access site entails. Central lines are preferred when short-term central venous access is indicated, and are commonly inserted by surgeons, intensivists, or interventional radiologists. In contrast, PICC lines are placed by specially trained nursing staff or interventional radiologists, and the logistics of insertion (scheduling, availability, and workload of the practitioners placing them) must be considered. The major benefit of PICCs is that patients can be discharged from the hospital with them, if prolonged access is required, and their safer insertion profile,

while the major advantage of traditional central venous catheters is that they allow infusion of vasoactive medications, and can be used for resuscitative purposes (administration of large volume of crystalloids rapidly) and advanced hemodynamic monitoring (measurement of central venous pressure). Both carry multiple ports, and it is a common practice to save one of these for nutrition access alone, as the high-carbohydrate concentration of nutrition solutions can act as a nidus for infection, if the same port is used both for TPN administration and is frequently accessed for blood draws. Both devices can also be used for administration of medications toxic to the peripheral venous system (e.g., hypertonic saline, vancomycin, and other hyperosmolar solutions), and allow an easy access route for repeat venous sampling, which can be convenient in patients requiring frequent laboratory draws. Routine exchange of uncomplicated central or PICC lines is not advocated, and both types of catheters should be removed when the indication for their placement ceases to exist, to minimize infectious and thrombotic complications.

Table 3-12 Recommendations for Clinical Nutritional Practice in the ICU

Recommendations for Clinical Nutritional Practice during Critical Illness
Enteral nutrition is always preferable to parenteral nutrition
Allow hypocaloric enteral feedings in the acute phase of critical illness for up to 5–7 days in previously well-nourished patients. Start as early as feasible
Routine glutamine supplementation is not supported during critical illness
Supply micronutrients to prevent refeeding syndrome, and monitor electrolytes, liver function tests, and triglyceride levels as needed

Adapted from Casaer MP, Van den Berghe G. Nutrition in the acute phase of critical illness. *N Engl J Med* 2014;370(13):1227–1236.

Peripheral parenteral nutrition (PPN) can be infused through peripheral venous cannulas. Peripheral intravenous feedings may be used for infusion of protein, lipid, and lower concentration dextrose solutions. PPN is limited in caloric delivery, due to the large volumes it would require to meet daily demands, but it avoids central venous cannulation, which has considerable complications. It can be considered for short-term parenteral nutrition, for example, in the case of postoperative patients with ileus expected to resolve in a few days.

Enteral feedings are typically administered through oro/naso-, -gastric or -enteric feeding tubes in the acute phase of disease. The stomach is easily accessed with a soft flexible feeding tube. Intragastric feedings provide several advantages compared to more distal gastrointestinal tract feedings, as the stomach has the capacity and reservoir for bolus feedings. Feeding into the stomach stimulates the biliary and pancreatic axis, with trophic benefits for the entire small bowel. Finally, gastric secretions exert a dilutional effect on tube feeding osmolarity, reducing the risk of diarrhea. An important risk of intragastric feedings is regurgitation of gastric contents with possible aspiration into the tracheobronchial tree. This risk is highest in patients with altered mental status or who are paralyzed. Placement of the feeding tube through the pylorus further down into the small bowel reduces the risk of regurgitation. Nasoduodenal/nasojejunal tubes are smaller in caliber and therefore more comfortable for patients, however, they are more prone to clogging. Patients who repeatedly remove their catheters may be candidates for feeding tube bridles. Placement of nasogastric or nasoduodenal tubes should always be confirmed radiographically prior to initiation of feedings.

Patients with chronically impaired mental status (such as those with severe traumatic brain injury), an inadequate swallowing mechanism or dysphagia, and those with oropharyngeal or proximal gastrointestinal tract pathology or recent/anticipated surgical procedure may be candidates for longer term transabdominal gastrointestinal access. This access is typically provided through temporary Stamm gastrostomies, in which a small laparotomy incision is made, and the gastric lumen in the midportion of the gastric body is accessed, while a transabdominal large-bore feeding tube is secured in place with concentric purse string sutures. Percutaneous endoscopic gastrostomy (PEG) tubes can be inserted and provide access for gastric feedings, without the need for laparotomy, general anesthesia, and even a trip to the operating room, as they can be performed at the bedside under endoscopic guidance. Using monitored anesthesia care, a gastroscope is advanced transorally into the stomach and helps transilluminate the anterior gastric wall through the abdominal wall. A small abdominal incision is made over the area of maximal transillumination, ideally over the midportion of the gastric body, and through an angiocath, a wire is advanced into the gastric lumen, which is snared and pulled back out of

the mouth with the gastroscope. The wire is looped around the PEG tube and pulled through the abdominal wall in an antegrade fashion, until only the head of the feeding tube remains in the stomach, with the rest of it being extracorporeal. The inner part of the PEG tube is confirmed to be in correct position and the feeding tube is secured in place. This technique may be difficult in obese patients, whose abdominal walls can be hard to transilluminate. Modified laparoscopy-assisted techniques have also been described.

Feeding jejunostomies can be considered following any major abdominal procedure, if the need for prolonged enteral nutrition is anticipated. A loop of proximal small bowel, typically 20 to 40 cm distal to the ligament of Treitz is elevated and secured against the abdominal wall fascia of the left upper or lower quadrant and is accessed transabdominally with a feeding tube. The tube can be covered for a short distance with bowel serosa (Witzel jejunostomy). Laparoscopic feeding jejunostomies have also been described, as well as the passage of jejunostomy tubes through percutaneously placed gastrostomy tubes.

ADDITIONAL NUTRITIONAL CONSIDERATIONS

Infectious Processes and Fever

As mentioned earlier, with core temperature elevations, such as those that occur with fever during infectious or other inflammatory processes, the base metabolic rate increases. Total energy requirements can be calculated using the aforementioned equations, multiplying by appropriate factors: mild to moderate infections increase energy requirements by 20% to 30%, and severe infection with fever increases caloric needs by over ~50% above basal levels. Even though weight gain and anabolism are difficult to achieve during the septic response, the astute clinician should be mindful of these associations and adjust nutritional support accordingly in persistently febrile patients.

Respiratory Failure

A condition commonly complicating surgical patients is respiratory failure with the need for prolonged mechanical ventilation. The main concern in mechanically ventilated patients is adequate gas exchange, which includes oxygen and carbon dioxide transport across the capillary–alveolar membrane. Not uncommonly the indication for ventilatory support is pulmonary infection, which along with a postoperative status, contributes to the overall hypermetabolism. Hypermetabolism is accompanied by increased oxygen consumption, which drives carbon dioxide production, as more substrate must be oxidized to support the greater energy requirements. While nutrition commonly takes lower priority in ventilated patients, in whom all efforts are directed toward managing the underlying etiology for the respiratory insufficiency, consideration should be given to the content of the nutritional support, as they may facilitate or prolong weaning, especially in those with chronic CO₂ retention. The RQ of a specific nutrient denotes the carbon dioxide produced over oxygen consumed, and adjustments in feedings from high RQ (e.g., carbohydrates, RQ = 1) to lower RQ (e.g., fat, RQ = 0.7), and avoidance of overfeeding should be considered in patients difficult to wean due to CO₂ retention. These adjustments have to be considered carefully, as increased fat intake, especially mixtures high in n-6 fatty acids, may exacerbate lung injury.

Renal Failure

Renal failure affects the body's ability to clear the byproducts of protein metabolism, but does not change the catabolic rate or the protein requirements. Therefore, a careful balance needs to be achieved between the need for protein and to limit uremia. When acute surgical stress is superimposed, consideration for potentially earlier or more aggressive renal support should be given, so that the body is not restricted of protein, which is critical during the hypermetabolic phase of acute disease. TPN with amino acids of high biologic value may improve survival in patients with acute renal failure.¹⁰⁴ The use of solutions containing high-quality amino acids can improve nitrogen balance and minimize urea production. This translates into a decreased frequency of dialysis.

Liver Failure

Patients with liver disease may be malnourished secondary to excessive alcohol intake, diminished food intake, or persistent inflammatory state from viral infection. These individuals are protein depleted, yet

tolerate protein poorly, due to their likelihood to become encephalopathic with high-nitrogen intake. Due to liver damage and portosystemic shunting, these patients develop derangements in circulating levels of amino acids. The plasma aromatic-to-branched chain amino acid ratio is increased, favoring the transport of aromatic amino acids across the blood–brain barrier. These amino acids are precursors of neurotransmitters that can worsen encephalopathy and lethargy. Using solutions enriched in BCAAs and deficient in aromatic amino acids in liver failure patients enhances protein tolerance and potentially improves in clinical encephalopathy.

Heart Failure

Myocardial dysfunction can be seen as part of the critical illness cardiomyopathy (circulating cytokines TNF and IL-1 appear to have a direct myocardial depressant activity) in patients with sepsis or those with preexisting congestive cardiac failure who undergo surgery. Patients with surgical emergencies commonly third space and require significant amounts of crystalloid resuscitation, which may exacerbate their pre-existing volume overload. When considering nutritional support of these patients, efforts should be made to minimize the total fluid volume, and nutrition formulas should be concentrated if possible.

Bariatric Surgery

Bariatric patients pose a special challenge, given their chronically overnourished status and their altered gastrointestinal tract, if they have undergone weight loss surgery. The latter are at increased risk for several macro- (usually protein) and micronutrient deficiencies (most commonly vitamins D and B₁₂, calcium, iron, folic acid, zinc, and selenium),^{105–107} and the clinician should be mindful of these potential complications. Nutritional support of the obese or postweight loss surgery patient is particularly complex because of the balance needed between minimizing overfeeding and avoiding the hypercatabolic state. Despite the excessive fat stores, critically ill obese patients should receive early and timely nutrition, as protein–calorie malnutrition does occur, and consideration for indirect calorimetry, which allows accurate estimation of the caloric requirements, and early involvement of a nutritionist should be considered. Hyperglycemia is an additional concern in obese patients, as glucose intolerance or frank diabetes may first manifest in acute illness, and should be addressed whenever identified.¹⁰⁸

Geriatric Patients

Attention to appropriate nutritional support of the geriatric patient is of paramount importance, both in the perioperative stage, as well as in the ICU, given the multiple physiologic alterations seen in older age, including greater ratio of fat-to-muscle mass, decreased cardiac and pulmonary reserves, poor dentition, polypharmacy, and high incidence of malnutrition, which may be as high as 85% in nursing home residents.^{109,110} In relation to preoperative preparation, elderly patients are more likely to have numerous disease processes affecting their general nutritional status, including diabetes, cancers, cardiac, pulmonary, and renal insufficiency. Given a certain degree of lean body mass loss is to be expected in this demographic, a higher-protein intake (>1.5 g/kg/day) should be the goal preoperatively in the elderly undergoing elective surgery, or early in the recovery phase after emergency procedure or acute surgical illness.⁴⁶ Toward that goal, numerous protein-rich supplements that are commercially available to patients who can tolerate enteral feedings, or parenteral nutrition with high-protein concentrations can be prescribed.⁴⁴

Enterocutaneous Fistulas

Gastrointestinal cutaneous or gastrointestinal atmospheric fistulas with high output (commonly defined as having output greater than 400 cc/24 hours) represent a classic indication for long-term TPN. Oral intake in patients with such fistulas typically results in greater output, especially in fistulas involving the proximal gastrointestinal tract, which can lead to dehydration, significant metabolic disturbances, and adversely affect the ability of the fistula to heal. TPN has been shown to increase spontaneous rate of closure of enterocutaneous fistulas by improving overall nutritional status in the host, or improving perioperative outcomes in those requiring surgical therapy. Somatostatin and analogs have been used to aid with fistulous output and spontaneous closure with varying results.

Short Bowel Syndrome

Patients with history of extensive small bowel resection lose a large part of the absorptive ability of the bowel, and frequently have to rely on prolonged TPN to meet their nutritional goals. In select patients with residual small intestine of at least 18 inches, postresection hyperplasia that can allow enteral nutrition has been demonstrated in subjects treated with supplemental glutamine, growth hormone, and a high-carbohydrate, low-fat TPN.¹¹¹

Major Thermal Injury

Burn victims often suffer from prolonged ileus, which encumbers enteral nutritional support. Even if the bowel is usable and patients not on mechanical ventilation, they are frequently unable to consume adequate calories, due to anorexia of severe injury and frequent npo status for repeated trips to the operating room. Currently available data suggest that aggressive nutritional support with high-protein intake in patients with major burns is associated with improved survival.¹¹²

Prolonged Postoperative Ileus

Patients undergoing major gastrointestinal procedures may develop prolonged ileus in the postoperative period, which precludes the use of the intestinal tract as a feeding route. If the patient is unable to eat by postoperative days 5 to 7, TPN should be considered. Although provision of TPN does not influence the disease process per se, it is beneficial because it prevents further erosion of lean body mass. When postoperative ileus of shorter duration is anticipated, patients can be bridged with PPN.

Acute Radiation and Chemotherapy Enteritis

Malnourished patients who receive abdominopelvic radiation or chemotherapy may develop mucositis and enterocolitis that precludes using the intestinal tract for nutrition for variable periods of time. In such individuals, parenteral nutrition should be provided, until the enteritis resolves and oral feedings can be resumed.

Chapter 4

Obesity and Metabolic Disease

Robert W. O'Rourke and Michael W. Mulholland

Key Points

- 1 Obesity is a polygenic phenomenon, and up to 70% of the propensity to a specific body habitus is due to genetic influences.
 - 2 Epigenetics and environment interact with genetics to produce the obesity phenotype.
 - 3 The hypothalamic feeding center is a dominant central site of control of energy homeostasis and receives multiple afferent inputs and delivers diverse efferent outputs to all organ systems.
 - 4 Control of food intake via satiety and hunger is a dominant mechanism of regulation of body weight, but other processes contribute, including but not limited to metabolic rate, adipocyte physiology, and the microbiome; alterations in the set-points and regulation of these processes have been linked to the development of obesity.
 - 5 Nutrient excess is a key early trigger in the development of cell stress that underlies the pathogenesis of metabolic disease.
 - 6 Adipose tissue acts as a critical nutrient “buffer” to protect other tissues from nutrient excess; as adipose buffering capacity is overwhelmed, nutrient excess overflows to all tissues, inducing metabolic disease.
 - 7 Hepatic steatosis and peripheral and central insulin resistance are dominant features of metabolic disease, but metabolic disease encompasses all organ systems with pleiotropic pathology.
-

GENETICS OF OBESITY

Metabolic thrift: Obesity is encoded within the human genome. The *thrifty gene hypothesis*, proposed by geneticist James Neel, posits that humans are predisposed to a *thrifty metabolism* by genes selected over eons of evolution in environments characterized by food scarcity.¹ These genes were adaptive in our ancient past but in our modern environment lead to a blossoming of obesity. In the past 50 years, the very genes which drive us to seek out calorie-dense food have led us to create, for the first time in human history, an *obesogenic environment* in which food is plentiful. While competing theories exist, such as predation release and genetic drift, Neel's thrifty gene hypothesis remains the basis of a modern understanding of obesity as a genetic phenomenon.

Metabolic thrift is a feature of all life, which exists in a perpetual struggle for energy resources. Strategies of metabolic thrift include high caloric intake, body temperature regulation, torpor, and hibernation. Humans practice thrift by storing energy in the form of adipose tissue. Lipid is not only energy dense, but also water insoluble, and thus can be stored in large quantities in cells without disrupting osmotic gradients. Because of these unique characteristics, virtually all life-forms use lipid as an energy storage molecule. Lipid droplets are found in yeast, *Drosophila* stores lipid in a specialized “fat body,” and migratory geese store lipid in hepatocytes. Humans, along with many other vertebrates, store large amounts of lipid in adipose tissue, which can provide energy for months; monitored fasts of over a year have been documented in obese humans.² Adipose tissue accumulation is not the only mechanism of human metabolic thrift. Insulin resistance is thought to have evolved in humans to protect against hypoglycemia during periods of fasting and famine. The *carnivore hypothesis* posits that insulin resistance appeared in primates with the onset of the ice age when food became scarce and primates shifted away from a carbohydrate-rich diet toward a protein-rich diet, an evolutionary heritage that explains the link between obesity and diabetes.

1 Modern genetics and human obesity: Compelling data support the contention that obesity is rooted in genetics. *Quantitative analysis of twin studies*, in which phenotypic traits of thousands of twin pairs are analyzed using statistical methods based on Mendelian principles, is a well-accepted method for

quantifying the contribution of genetics to a given phenotype or disease. Multiple twin studies have consistently demonstrated that approximately 70% of the tendency toward obesity is due to genetics, with the remainder presumably due to environmental influences.³ *Genome-wide association studies* extend these data and permit study of human genetics at the nucleotide level. These studies involve sequencing the genomes of thousands of patients and correlating single-nucleotide polymorphisms (SNPs) with phenotypic traits and disease states. Association studies have begun to identify the thrifty genes that Neel postulated decades earlier. Many SNPs that correlate with obesity lie within genes that are directly associated with body weight regulation. Others lie in genes that are not as clearly related to energy balance, including genes that regulate neural and limb development, DNA repair, and many other cellular functions, testament to the fact that the processes that regulate energy homeostasis overlap with all aspects of physiology. As SNP data emerge, it has become clear that the effect size of each individual SNP's contribution to the obesity phenotype is small, on the order of <1% to 3%, and that potentially hundreds of SNPs contribute to obesity. Obesity, like many chronic diseases, is a complex polygenic phenomenon. Genetic studies have so far identified over 50 SNPs that correlate with human obesity, and the list continues to grow.⁴

2 Epigenetic mechanisms contribute to obesity. The *thrifty phenotype hypothesis* was proposed by Hales and Barker in 1992 to explain the observation that infants born to malnourished mothers are at increased risk of adult obesity and metabolic disease compared to offspring born of the same mothers during well-nourished pregnancies.⁵ The fetus was presumed to be responding to instability in environmental food resources by adjusting its phenotype toward a thrifty metabolism, a phenomenon termed *fetal programming*. A similar response was subsequently observed in fetuses born of obese and diabetic mothers.⁶ Excess or scarcity of nutrients may be interpreted similarly by the fetus as signs of unstable food resources, which may explain the similar effect of maternal under- and overnutrition on offspring metabolic phenotype. Subsequent research has demonstrated that these effects are mediated by epigenetic mechanisms which involve covalent modification of DNA independent of changes in Watson–Crick base-pair sequence, including DNA methylation and glycosylation and histone modification. These changes may persist for one or more generations. Research over the past two decades has revealed that epigenetic modification of the genome is widespread, occurs primarily during fetal development but may extend into adulthood, and regulates normal developmental and homeostatic processes as well as pathologic responses. Epigenetics allows the fetus to respond in utero to environmental cues delivered by changes in maternal homeostasis, the so-called “weather forecast” model.⁷ Epigenetic modifications in response to fetal under- and overnutrition have been demonstrated in animals and humans, play an important role in disease pathogenesis, and speak to the fact that intervention must occur early, prior to birth, to prevent adult obesity and metabolic disease. The metabolic dice are cast *in utero*.

Human metabolic diversity and the role of environment: The multiple thrifty SNPs in the human genome impart marked genetic heterogeneity that underlies the intrinsic variability of the human body habitus, with a wide range of body types from lean to obese. This heterogeneity extends to all aspect of metabolism, with individual differences in satiety and hunger thresholds, metabolic rates, metabolic handling of lipid and glucose, variability in adipocyte proliferation and hypertrophy capacities, and differing propensities to insulin resistance and hyperlipidemia. This heterogeneity explains the diversity of the obesity phenotype with its different sites of accumulation, including visceral and subcutaneous, and its variable ages of onset, triggers, severity, and responses to diet- and surgery-induced weight loss. The human species is highly metabolically diverse, a trait that had been critical to our success, allowing us to adapt to a wide range of habitats as we colonized the globe. Multiple examples exist of human subpopulations whose genetic heritages are adaptive in their native environments, but maladaptive in a modern obesogenic environment. Polynesians provide an example of a human subpopulation with a marked genetic propensity to obesity and insulin resistance, traits that provided a selective advantage in the ancient South Pacific environment, which was characterized by labile food supplies and transoceanic voyages that entailed a high risk of starvation. This genetic heritage, in our modern environment, places Polynesians at exceptionally high risk for obesity and metabolic disease. Similar human subpopulations metabolically adapted to specific niche environments but at high risk for metabolic disease in industrialized society include Inuit Eskimos, Aboriginal Australians, and Pima Indians (Fig. 4-1).

Environment plays a critical role in the pathogenesis of obesity. Dominant modern environmental contributors are an excess of processed food and a structured *built environment* that discourages physical activity. Modern processed food is not only calorie dense but also highly palatable, and stimulates central nervous system (CNS) reward centers and hunger/satiety circuits not designed for chronic

stimulation, thus reinforcing overeating. Physical activity is markedly decreased in our modern environment relative to our distant past. Paleolithic humans were estimated to have consumed 30% more calories than modern humans but engaged in significantly higher levels of physical activity.⁸ Other factors also contribute to a lesser extent, including disruption in Circadian rhythms, stability in home temperatures, and assortative mating patterns. An evolving field of environmental engineering has arisen to address these issues.

Figure 4-1. Interactions between environment and genetics dictate phenotype. **A:** Environment alters genetics over millennia, while the effects of environment on epigenetics take place over generations. In the case of humans, genetics dictates our behavior which in turn has led us to create an obesogenic environment, creating a vicious cycle that exacerbates the obesity epidemic. **B:** The obesity phenotype blossoms in a modern obesogenic environment, with the population body mass index (BMI) curve broadening and shifting rightward, with an increase in median BMI. The increase in median BMI is relatively modest, but a substantially larger percentage of people populate overweight and obese BMI ranges. Of note, the schematic graphs shown are similar to those that describe the shift in US population BMI National Health and Nutrition Examination Survey data from the late 1970s to the early 2000s.

PHYSIOLOGY OF OBESITY

3 The adipostat: A dominant determinant of systemic metabolic homeostasis is the quantity of existent adipose tissue stores, the adequacy of which is determined by the hypothalamic feeding center (HFC). The HFC receives multiple afferent neural and hormonal inputs from all organ systems, including adipose tissue, and orchestrates a range of responses via efferent outputs that regulate all aspects of metabolism. These multiple HFC-regulated systems monitor and maintain adipose tissue stores, and together comprise the *adipostat*, the sum total of all processes that defend body weight. The amount of adipose tissue deemed adequate by the HFC varies among individuals and is dictated by multiple poorly understood thrifty genes. Collectively, these genes and the proteins they regulate define the *adipostat set-point*, which determines the degree of metabolic thrift of an individual. The hypothalamus of a lean person “considers” a lower amount of adipose tissue to be adequate, while the hypothalamus of an obese person requires higher levels of baseline adipose tissue stores. Weight loss alerts the HFC to deviation from the adipostat set-point and triggers robust compensatory metabolic responses that act to restore adipose tissue mass to baseline levels, including but not limited to increased hunger, decreased satiety, and decreased metabolic rate. The HFC resides deep in the midbrain, far removed from the frontal cortex, the seat of conscious thought and what we refer to as “willpower.” HFC-mediated metabolic responses are characterized by tight regulation; deviation outside the range of these responses for more than limited periods of time is not possible based on conscious choice, explaining the near-universal failure of conscious dietary efforts to lose weight. Obese patients are able to control their weight only to a point, and only for brief periods, after which compensatory responses are activated. These mechanisms also explain the lack of efficacy of liposuction as a tool for weight loss. Regardless of the method, whether diet-induced or liposuction, reduction in adipose tissue mass activates compensatory mechanisms that act to restore adipose tissue mass to set-point levels. Bariatric surgery-

induced weight loss is the only exception to this rule, inducing poorly understood paradoxical responses that bypass the adipostat, including decreased satiety and increased metabolic rate.

Multiple physiologic mechanisms comprise the adipostat and regulate body weight. Most important in humans are the collective satiety and hunger systems that regulate food intake. Less powerful but nonetheless important are mechanisms that control metabolic rate, adipocyte physiology, and the microbiome.

4 Satiety and hunger: Regulation of food intake is the dominant mechanism by which humans control body weight. This is not true for all species. While food intake is an important mechanism of energy homeostasis in mice, regulation of metabolic rate plays a greater role in mice than in humans. Food intake in humans is controlled by a family of proteins that regulate satiety and hunger primarily by acting on receptors within the hypothalamus. These diverse proteins are secreted by multiple organ systems, including but not limited to adipose tissue, the gut, the liver, and the skeletal muscle.

The Ob mouse, a genetic mutant strain described in 1950, manifests an obese phenotype, along with a range of other abnormalities related to immune, endocrine, and reproductive functions. The Ob mouse harbors an inactivating point mutation in the *leptin* gene (Gr. *leptos*, thin). Leptin is a 16-kD satiety hormone secreted by adipose tissue in response to a meal that in turn acts on receptors within the HFC to induce satiety. Leptin establishes communication between adipose tissue, the gut, and the brain that signals the status of adipose tissue stores to the brain, which in turn dictates food intake. As such, leptin represents a paradigmatic mediator of the adipostat, and an example of the complex interorgan communication that underlies its function (Fig. 4-2). Soon after the cloning of the leptin gene in 1994,⁹ rare humans with leptin mutations were identified with an Ob phenotype that was reversed with administration of exogenous recombinant leptin. Unfortunately, similar therapy was ineffective in common human obesity, which is not due to a single-leptin mutation, but rather is polygenic and characterized by hypothalamic resistance to leptin satiety effects. Nonetheless, the discovery of leptin led to an explosion of satiety and hunger research, and over the ensuing decade multiple satiety and hunger proteins were described.

Figure 4-2. Leptin mediates communication between adipose tissue, gut, and brain. A: Signals from the gastrointestinal tract

triggered by a meal circulate to adipose tissue and induce adipocyte leptin secretion. Leptin circulates to the hypothalamus, where it binds receptors in the arcuate nucleus to induce satiety, leading to decreased food intake. Leptin is one of many signals that mediates bidirectional communication between gut, adipose tissue, and brain. Other organ systems are also involved, including immune and reproductive systems and the liver. **B:** Leptin regulates allostatic control of short-term and long-term food intake. Postprandial leptin secretion induces satiety for a period of hours, after which leptin levels and satiety wane, prompting food intake. Similarly, leptin, along with other mediators of food intake, controls long-term weight regulation: diet-induced weight loss leads to decreased adipose tissue mass, reducing peak postprandial leptin levels, leading to decreased postprandial satiety and increased food intake at each subsequent meal until adipose tissue mass is restored to set-point levels. In this manner, leptin functions as a component of the adipostat. This allostatic control provides an explanation for rebound weight gain after diet-induced weight loss.

The control of feeding behavior and nutrient intake is a highly regulated process centered in the hypothalamus, which integrates information regarding nutritional status, environment, and energy expenditure via central and peripheral orexigenic and anorexigenic signals. Peripheral messengers include signals from adipose tissue (*adipokines*), including leptin and adiponectin, *cytokines*, such as TNF- α and interleukin (IL-6), and *gut peptides*. Among this diverse latter class of mediators, ghrelin is a dominant stimulant of feeding. Ghrelin is expressed primarily by oxyntic glands in the fundus of the stomach. Gastric ghrelin-producing cells represent about one-fourth of endocrine cells within the gastric mucosa. Ghrelin is also produced in the hypothalamus.

Encoded by five exons, preproghrelin undergoes endoproteolytic processing and posttranslational modification to yield des-acyl ghrelin and acyl ghrelin. Both hormones share the same amino acid sequence, and both are detectable in blood, but acyl ghrelin, which undergoes acylation of the Ser3 residue, is the active form. Acyl ghrelin regulates feeding, metabolic activity, and insulin secretion. The enzyme-mediating acylation is the membrane-bound ghrelin O-acyltransferase (GOAT). Genetic disruption of the GOAT gene in mice leads to complete absence of acyl ghrelin. GOAT inhibition improves glucose tolerance and reduces weight gain in mice. Plasma acyl-ghrelin levels increase with fasting and decrease after feeding, a pattern indicating that ghrelin is involved in meal initiation. The ghrelin receptor is a member of the family of G protein-coupled receptors and contains seven transmembrane domains. Ghrelin receptors are widely distributed among both central and peripheral tissues, including the pituitary gland, hypothalamus, pancreas, stomach, and intestine. Ghrelin causes growth hormone secretion following peripheral or central administration, and release of growth hormone from cultured pituitary cells.

Ghrelin is the only orexigenic hormone identified to date. The relative scarcity of orexigenic proteins relative to anorexigenic proteins underscores an important fundamental characteristic of the global regulation of food intake, which is biased toward chronic basal hunger regulated by multiple satiety factors (rather than chronic basal satiety regulated by multiple hunger factors). This central feature of food intake control systems predisposes to excess food intake and thus provides a selective advantage in environments of food scarcity during our evolution, but leads to obesity in our modern environment. In humans, the intravenous administration of ghrelin at physiologic concentrations induces the sensation of hunger and stimulates oral intake. Circulating ghrelin levels peak just prior to meal initiation and decline rapidly postprandially. Ghrelin secretion is increased by weight loss and by restriction of caloric intake. Serum ghrelin levels are increased in anorexic individuals and depressed in obese subjects. In animals, ghrelin administration has been found to stimulate food intake, to induce growth of adipose tissues, and to increase body weight. The administration of ghrelin antibody or ghrelin receptor antagonists blunts ghrelin-induced weight gain and positive energy balance. Similar molecules are under active study as potential therapeutic agents.

Ghrelin is a circulating hormone with CNS effects. The arcuate nucleus of the hypothalamus is a crucial site for the integration of fasting and feeding signals. Two types of neurons, with opposing actions on feeding behavior, have been identified in the arcuate nucleus. Neurons that express proopiomelanocortin and cocaine- and amphetamine-regulated transcript (CART) suppress food intake, reduce body weight, and increase energy expenditure. In contrast, neurons producing neuropeptide Y and agouti gene-related transcript (AgRP) are orexigenic. These cells act to stimulate food intake and reduce energy expenditure. Ghrelin, as well as leptin and multiple other gut peptides, adipokines, and cytokines, directly mediate the activities of these two types of neurons (Fig. 4-3). Direct peripheral effects of ghrelin on peripheral tissues also contribute to the regulation of body weight and energy homeostasis.

Leptin and ghrelin are paradigmatic adipokine and gut peptide mediators of food intake respectively,

but multiple other proteins contribute. Adipokines that regulate satiety include adiponectin, visfatin, apelin, and lipocalin; gut peptides include glucose-dependent insulintropic peptide (GIP), glucagon-like peptide-1 (GLP-1), nesfatin-1, oxyntomodulin, pancreatic polypeptide, cholecystokinin, amylin, glucagon, somatostatin, cholecystokinin, and insulin. Finally, cytokines, including TNF- α and IL-6, in addition to immunoregulatory functions, also play important roles in the control of food intake. TNF- α , for example, mediates anorexigenic responses in the context of cachexia and inflammatory states. Virtually all adipokines, gut hormones, and cytokines have multiple overlapping functions that include regulation of satiety and hunger, immune function, glucose homeostasis, lipid metabolism, and endocrine and reproductive function (Fig. 4-4). This functional diversity speaks to the intimate association of energy homeostasis with all aspects of physiology.

Genetic polymorphisms in the melanocortin 4 receptor gene, which regulates satiety and hunger responses and the HFC set-point, are implicated in 5% of cases of human obesity. Similar polymorphisms associated with obesity exist with the genes encoding leptin and its receptor, ghrelin, neuropeptide Y, adiponectin, GLP-1, and other genes associated with the control of satiety and hunger. These observations demonstrate that variability in the genes that regulate food intake, with corresponding variability in the functional control of satiety and hunger, contribute to the development of human obesity.

Metabolic rate: While less important than control of food intake, variability in metabolic rate contributes to the pathogenesis of obesity. In obese subjects who lose weight with diet, total energy expenditure is decreased up to 20% beyond that expected by loss of fat and fat-free mass alone, and is accompanied by a corresponding decrease in voluntary physical activity.¹⁰ In contrast to diet-induced weight loss, bariatric surgery-induced weight loss paradoxically induces increased energy expenditure, which may explain the efficacy of surgery. In the absence of surgery however, compensatory decreases in energy expenditure counteract caloric restriction and contribute to adipostat responses that resist declines in adipose tissue mass. Studies of overfeeding and weight gain in obese subjects demonstrate converse changes with a compensatory increase in total energy expenditure. Importantly, overfeeding studies in twin cohorts demonstrate a significant genetic component to variability in energy expenditure responses to overfeeding, suggesting that variability in metabolic rate responses to weight loss contributes to the development of obesity in those at risk.³

Differences in sympathetic nervous system activity are observed in humans and represent a potential mechanism underlying variability in metabolic rate. Obese humans demonstrate decreased sympathetic nervous system activity compared to lean humans, and higher levels of sympathetic nervous system activity predict successful diet-induced weight loss. Differences in endocrine responses also contribute, with obese humans manifesting differences in thyroid hormone and catecholamine balance associated with decreased metabolic rates. At the cellular level, differences in energy utilization and thermogenesis play an important role. Skeletal muscle energy utilization efficiency is increased in humans who achieve successful weight loss and decreased in those who gain weight. Furthermore, decreased levels of skeletal muscle nonexercise-induced thermogenesis and diet-induced thermogenesis have been demonstrated in obese humans.¹¹ These observations suggest that fundamental differences in cellular energy homeostasis contribute to obesity. The mechanisms underlying these variable cellular responses are not fully defined, but differences in uncoupling protein (UCP) function are implicated. UCPs uncouple oxidative phosphorylation from electron transport in mitochondria, creating a proton leak that generates heat rather than ATP. The role of UCPs in the pathogenesis of obesity is an important area of active research. UCP function is highly variable and genetically determined in mice, and polymorphisms in UCP genes correlate with obesity and metabolic disease in humans, supporting a role for genetic variability in UCP function in obesity pathogenesis. Transgenic mice overexpressing UCP-1 under control of the adipose tissue-specific AP2 promoter are resistant to obesity, suggesting the potential therapy for obesity based on manipulation of cellular thermogenesis and metabolic rate.

Figure 4-3. A simplified schematic of the hypothalamic feeding center and its primary afferent signals. **A.** Multiple hormones secreted by the gastrointestinal tract and adipose tissue act as afferent signals that impact on the arcuate nucleus (ArcN) within the hypothalamic feeding center to regulate feeding behavior. **B.** Peripheral afferent signals impact on first-order ArcN neurons, which in turn communicate with second-order paraventricular nucleus (PVN) and lateral hypothalamic area (LHA) neurons to coordinate behavioral and metabolic output. PVN signaling is primarily anorexigenic and catabolic, and is enhanced by leptin and insulin, while LHA signaling is primarily orexigenic and anabolic and inhibited by leptin and insulin. Higher-order anorexigenic PVN outputs include corticotropin-releasing hormone (CRH), oxytocin, and thyrotropin-releasing hormone (TRH); higher-order orexigenic LHA outputs include melanin-concentrating hormone (MCH) and orexins A and B. Both pathways negatively regulate the other. Other peripheral and central mediators stimulate first- and second-order neurons as well, including ghrelin, CCK, GLP-1, serotonin, endogenous cannabinoids, and norepinephrine.

Adipocyte physiology: Adipocytes arise from mesenchyme-derived adipocyte stem cells within adipose tissue. Nomenclature is evolving and includes the terms *preadipocyte* or *adipocyte/adipose tissue stem cell*. Adipocyte stem cells are pluripotent, and depending on the stage of differentiation, may give rise to adipocytes, fibroblast, myocytes, and other cell types. Multiple adipocyte stem cell subpopulations give rise to adipocytes of variable phenotypes, including white, brown, and beige. Evidence suggests that hematopoietic precursor cells may also give rise to adipocytes.

Until recently it was thought that adipocyte stem cell proliferation, that is, hyperplasia, did not occur in postnatal humans, and that adipocyte hypertrophy was the primary mechanism of increased adipose tissue mass in obesity. Recent data suggest that both hyperplasia and hypertrophy contribute to evolving obesity, with hyperplasia predominating during childhood and hypertrophy predominating during adulthood. These data derive in part from ingenious methods studying incorporation of C14 into adipocyte DNA in individuals born before and after mid-20th century nuclear bomb testing, which raised environmental C14 levels.¹² Data over the last decade have demonstrated that adipocyte hyperplasia and proliferation are highly regulated and that aberrations in these processes contribute to obesity. Adipocyte necrosis and apoptosis as a result of hypoxia and nutrient excess (described below) are matched by increased adipocyte stem cell proliferation and differentiation. Furthermore, adipocytes from obese humans demonstrate increased hyperplastic and hypertrophic capacities, contributing to increased adipose tissue mass with progressive obesity.¹³ The epigenetic programming of adipocyte stem cells during fetal development may underlie some of these differences in adipocyte behavior observed between obese and lean subjects. Defining regulatory mechanisms of adipocyte growth is an active area of research and will lead to methods to manipulate adipocyte biology and treat obesity at its source.

Figure 4-4. Primary peptide mediators of energy homeostasis. Cytokines, adipokines, and gut peptides regulate diverse aspects of metabolism to control global energy homeostasis. Each of these proteins has dominant functions within its primary family, but also demonstrates cross-regulatory functions in other domains. In addition, mediators participate in crosstalk at the level of cellular receptors and downstream intracellular signaling mediators. Shown are only partial lists of peptides and the physiologic functions they control.

The microbiome: In a very real sense, the microbiome may be considered a distinct organ system much like cardiopulmonary, gastrointestinal, or renal systems, and like any organ system, aberrations in the microbiome contribute to the pathophysiology of disease. The microbiome plays an important role in energy homeostasis. Animals raised in germ-free environments manifest increased food intake but decreased body weight and do not develop obesity and insulin resistance when fed a high-fat diet, demonstrating that gut microbiota contribute to nutrient digestion. Gut microbiota ferment nonhost-digestible polysaccharides into absorbable monosaccharides and short-chain fatty acids that are absorbed by host enterocytes and colonocytes. Products of microbiota fermentation act not only as nutrients, but also regulate host metabolism: short-chain fatty acids induce host satiety, mediated in part by increased secretion of GLP-1 and peptide YY and decreased secretion of ghrelin. Separate data demonstrate interactions between microbiota and adipose tissue, liver, skeletal muscle, and CNS. These effects are mediated by short-chain fatty acids, activation of Toll-like receptors on host cells via lipopolysaccharide and other bacterial products, regulation of host systemic and cellular metabolism, and other diverse mechanisms, all of which affect diverse aspects of host energy homeostasis.

Alterations in microbiome–host interactions contribute to the pathogenesis of obesity and metabolic disease. Germ-free mice, when colonized with stool from obese mice, gain more weight than mice colonized with stool from lean mice, demonstrating an obesity-specific microbiome. The ratio of gut Firmicutes/Bacteroidetes species is increased in obese mice and humans. Ongoing research has begun to identify specific subspecies within these broad categories of bacteria that are altered in obesity and metabolic disease to provide a higher-resolution picture of the microbiome in obesity. For example, obesity in mice and humans is associated with an increase in gram-negative gut bacteria, with a concomitant increase in lipopolysaccharide absorption from the gut, which has been postulated to contribute to obesity-associated inflammation and insulin resistance. The tools used to evaluate the microbiome are rapidly evolving. Sequencing of the microbial genome using ribosomal 16S is well established, while evolving technologies include shotgun sequencing of the entire metagenome and functional assays involving transfer of human microbiota in the form of stool into germ-free animals to study in vivo effects. Manipulation of the microbiome holds significant promise. Prebiotic (nondigestible bacterial nutrients) and probiotic (specific bacterial subspecies thought to confer systemic benefits) therapies are areas of active research, while antibiotic therapy directed against gram-negative bacteria reduces steatosis and systemic inflammation in obese rodents.

Summary: Satiety and hunger, metabolic rate, adipocyte physiology, and the microbiome are but a few of the many processes that regulate metabolism and are dysregulated in obesity. Differences in lipid and glucose metabolism, immune function, central and peripheral nervous system function, and multiple other processes that impact upon energy metabolism contribute to the wide variability of the obesity phenotype in humans. This variability is the result of genetic polymorphisms that contribute to metabolic diversity among humans and the wide range in human body habitus. The question is often posed as to whether obesity should be considered a disease. Rather, obesity is better thought of as a

maladaptive compensatory response to an environment that is radically different than that in which our species evolved. The obesity phenotype remained relatively underexpressed in environments of food scarcity in which we evolved, in which obesogenic genes acted to defend adipose tissue stores and enhance survival, but blossoms in our modern environment. An understanding of this intimate interplay between phenotype and environment will lead to novel therapy for obesity based on manipulation of environment and genetics.

PATHOPHYSIOLOGY OF METABOLIC DISEASE

Obesity and metabolic disease: Obesity is associated with a range of pathology involving every organ system collectively referred to as metabolic disease. While underlying mechanisms are multiple, the root cause of all metabolic disease is a failure of adipose tissue nutrient buffering capacity, leading to overflow of nutrients, metabolites, cytokines, and adipokines from adipose tissue to other tissues. The clinical effects of overflow differ depending on the target tissue, but the fundamental cellular responses to nutrient excess common to all tissues, adipose included, involve mechanisms by which cells control nutrient flux and respond to nutrient excess. These cellular responses underlie the pathophysiology of metabolic disease.

5 Metabolism, nutrient excess, and the root cause of metabolic disease: Energy homeostasis is the dominant and overriding goal of all biologic systems. Metabolism (Gr. *metabole*, change) may be defined as the sum total of all chemical reactions and physiologic processes that regulate cellular and systemic energy homeostasis. At the cellular level, metabolic processes are fundamental to all metazoan life and are highly conserved across phyla; examples include the citric acid cycle and mitochondrial respiration, which utilize multiple enzymes, the structure and function of which are conserved from yeast to humans. At the systemic level, metabolic processes are central to maintaining homeostasis and interface with virtually with every organ system and every physiologic process. The basic substrates of metabolism are the macro- and micronutrients that comprise the stuff of cells and tissues, the fatty acids, amino acids, and carbohydrates and their derivatives that are the constituents of complex macromolecules, and the micronutrients that contribute to the catalysis of reactions that synthesize and degrade macronutrients and higher-order macromolecules. In one sense, all cells are simply clearinghouses for nutrients. Cellular nutrient flux provides substrate for synthesis of macromolecules via anabolic metabolic processes, which are in turn degraded via catabolic metabolic processes. Maintaining the balance between anabolism and catabolism at cellular and systemic levels is of critical importance. Cancer, for example, may be viewed as a metabolic imbalance that favors cellular anabolism over catabolism. Cachexia, in contrast, may be considered as a metabolic disorder that favors systemic catabolism over anabolism.

The nutrient flux with which cells are constantly faced determines the balance between anabolism and catabolism and dictates organism-wide energy homeostasis. Nutrients are, by their very nature, high-energy capacity molecules, much like oxygen, and like oxygen, are capable of participating in energy-intensive and potentially damaging reactions. Fatty acid metabolites such as ceramides and diacylglycerols, and glucose metabolites including advanced glycation end products and glucosamines, trigger inflammation, oxidative stress, and insulin resistance at the cellular level.

Excess nutrients are therefore potentially damaging to cells, and cellular physiology has evolved processes designed to control exposure, flux, and sequestering of these high-energy molecules. These cellular processes were selected by evolution to manage *transient* nutrient excess, but are not well adapted to manage *chronic* nutrient excess, a situation that cells only rarely encountered during evolution. Maladaptive cellular responses to chronic nutrient excess underlie the pathogenesis of all obesity-related disease and occur in all cells, explaining the involvement of virtually every organ system in metabolic disease. These processes consist of a triumvirate of fundamental cellular stress responses: *endoplasmic reticulum (ER) stress, oxidative stress, and inflammation*.

Cellular responses to excess nutrient flux: The ER is a complex organelle present in virtually all eukaryotic cells that orchestrates synthesis, folding, and intracellular transport of macromolecules. The rough ER, studded with ribosomes, is predominantly responsible for protein synthesis, while the smooth ER is predominantly responsible for lipid and carbohydrate synthesis. The ER receives a constant influx of nutrient substrates, which it sequesters and directs toward macromolecule synthesis or degradation, thus carefully metering cellular nutrient exposure. In this capacity, the ER acts as a nutrient sensor, responding to changes in cellular nutrient flux by directing cellular anabolism and catabolism accordingly. The ER also responds to other cell stressors, including hypoxia, toxins, disturbances in

electrolyte or micronutrient balance, and a host of other stimuli that alter cell homeostasis. Excess cellular nutrient flux, like other forms of stress, leads to a series of stepwise ER responses that are collectively referred to as the ER stress response.

The initial ER stress response to modest increases in nutrient flux involves increased expression of *chaperone proteins* involved in macromolecule synthesis to accommodate increased anabolism of excess nutrients. If nutrient excess persists to exceed the capacity of cellular macromolecule synthesis and nutrient sequestration, the ER stress response progresses to activate the *unfolded protein response*. The unfolded protein response downregulates global protein expression while upregulating expression of chaperone proteins in an adaptive response designed to maintain synthesis of essential cellular proteins. If nutrient excess persists beyond the capacity of the ER to maintain proper protein synthesis, then the unfolded protein response progresses to induce cell apoptosis. The unfolded protein response thus protects cells from modest increases in nutrient flux and induces cell death in the face of extreme nutrient excess.

The ER stress response is not the only cellular response to nutrient excess. Macromolecule synthesis generates reactive oxygen species (e.g., superoxides, oxygen/hydroxyl-free radicals, hydrogen peroxide) which, like nutrients, are highly energetic molecules capable of damaging cells. Cells have evolved multiple mechanisms to sequester reactive oxygen species and manage oxidative stress, including antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, scavenging molecules such as ascorbic acid, urate, and divalent ions, and the thioredoxin and glutaredoxin systems. The ER and mitochondria are primary cellular sites of control of oxidative stress. When nutrient flux, macromolecule synthesis, and reactive oxygen species production exceed cellular antioxidant capacity, cells activate diverse oxidative stress responses, which increase expression of antioxidant proteins, sequester reactive oxygen species, and increase mitochondrial uncoupling, which transiently reduces cellular reactive oxygen species production. Oxidative stress responses overlap with ER stress responses, and if oxidative stress persists, the unfolded protein response is activated and leads to apoptosis.

The third arm of the cellular stress response is inflammation. Increased nutrient flux generates an inflammatory response designed to scavenge debris and byproducts from increased cell turnover and macromolecule synthesis that result from ER and oxidative stress responses. Testament to the close relationship between metabolism and inflammation, central inflammatory and metabolic mediators demonstrate marked functional overlap. For example, TNF- α and leptin, in addition to their dominant functions in regulating inflammation and satiety respectively, each plays important reciprocal roles in regulating body weight and inflammation.^{14,15} TNF- α and leptin are but two examples of many satiety and hunger factors and inflammatory cytokines that manifest dual immunoregulatory and energy homeostasis functions. In addition, molecular byproducts of metabolism trigger inflammation. Free fatty acids are ligands for Toll-like receptors, while advanced glycation end products trigger receptors of advanced glycation end-products pathways which directly activate innate immune effector cells, establishing a direct molecular link between metabolism and inflammation. Obesity is associated with a state of chronic systemic inflammation that plays a central role in the pathogenesis of multiple comorbid diseases. Serum cytokine levels are increased in obese animals and humans, and adipose tissue manifests a pan-leukocyte infiltrate, findings that directly correlate with the magnitude of obesity and severity of metabolic disease.

Increased ER stress, oxidative stress, and inflammation have been demonstrated in obese rodents and humans. An important aspect of cellular stress responses is that each potentiates the others via overlap in fundamental cell signaling pathways including PI3-Akt, MAPK, AMPK, mTOR, JAK-STAT, and NF κ B. These signaling pathways are triggered by multiple stimuli that are dysregulated in obesity, including adipokines, cytokines, growth factors, and nutrients and metabolites. Furthermore these signaling pathways participate in robust crosstalk at multiple levels, establishing a vicious cycle that perpetuates cell stress in the face of chronic nutrient excess (Fig. 4-5). These processes are common to all cells and affect all tissues in late-stage obesity, explaining the diverse manifestations of systemic metabolic disease. But where do these processes begin, and what initiates them? To answer this question, we must explore the early events in adipose tissue in evolving overweight and obesity – it is within adipose tissue that metabolic disease originates.

Adipocyte hypertrophy, hypoxia, inflammation, and fibrosis: Adipocytes are exquisitely well designed to manage high levels of nutrients. One of the first responses of adipocytes to chronic elevations in nutrient flux in early overweight and obesity is hypertrophy. Free fatty acids are absorbed by adipocytes through pinocytosis mediated by fatty acid-binding proteins, as well as being synthesized from glucose and glutamine via de novo lipogenesis, and stored in lipid droplets via a highly regulated

process mediated by perilipin proteins. Virtually all cells are capable of storing lipid to some degree, but adipocytes have an extremely high capacity for lipid storage and hypertrophy. Adipocytes are one of only a few cell types that can enlarge to diameters greater than 100 microns, the diffusion distance of oxygen. Adipocyte diameter in humans correlates directly with the magnitude of obesity and the severity of metabolic disease; adipocytes in lean subjects are virtually all less than 100 microns in diameter, while those in obese subjects are greater than 100 microns, in some cases exceeding 200 microns.¹⁶ Progressive adipocyte hypertrophy establishes a state of cellular hypoxia within adipose tissue that has been verified in obese mice and humans. Decreased adipose tissue capillary density and blood flow in obesity exacerbate hypoxia. This hypoxic state has broad effects on adipocyte metabolism, inducing insulin resistance, ER stress, oxidative stress, and inflammation, and inhibiting lipogenesis. Manipulation of hypoxic responses in adipocytes holds therapeutic promise. For example, targeting hypoxia-inducible factor-1 α , a dominant cellular hypoxia-response protein, in murine obesity ameliorates metabolic disease.¹⁷

Hypoxia induces adipocyte apoptosis and necrosis which in turn recruits an inflammatory response designed to scavenge dead and dying adipocytes. This inflammatory state is a dominant aspect of adipose tissue dysfunction in obesity, and is directly linked to insulin resistance and dysregulation of lipid metabolism at local (adipose tissue) and systemic levels. Central to adipose tissue inflammation is a marked accumulation of adipose tissue macrophages (ATMs), the number of which directly correlates with the degree of obesity in mice and humans. ATMs are important mediators of metabolic disease, and are altered in phenotype, shifting from a scavenging M2 phenotype to an inflammatory diabetogenic M1 phenotype.¹⁸ ATMs are a dominant source of inflammatory cytokines, including TNF- α , IL-6, and IL-1, all of which induce insulin resistance and aberrations in glucose and lipid metabolism in adipocytes via multiple mechanisms. In support of a central role for ATMs in the pathogenesis of metabolic disease, mice transgenically engineered to lack macrophage homing molecules in adipose tissue do not develop obesity-related ATM infiltrates and are protected from diabetes. Preliminary trials of pharmacologic agents that interfere with macrophage homing to adipose tissue in humans show promise as treatment for diabetes. Finally, adipose tissue inflammation in obesity involves more than macrophages, and is associated with a pan-leukocyte infiltrate that includes T-cells, B-cells, NK cells, NKT cells, and eosinophils. Therapy for metabolic disease based on nonmacrophage cellular immune mediators is an area of active research.

Figure 4-5. Highly simplified schematic of major cell signaling pathways that regulate energy homeostasis and cell stress responses. Primary stimuli for all cells include adipokines, insulin, IGF-1, nutrients and metabolites including free fatty acids, and their derivatives such as ceramide (which activate Toll-like receptors, TLR), glucose, fructose, and advanced glycation end products (which activate receptors for advanced glycation end products, RAGE), and cytokines. Primary intracellular signaling nexi include mitogen-activated protein kinases (MAPK), PI3-Akt, JAK/STAT signaling mediators, AMP-activated protein kinase (AMPK), mammalian target of rapamycin (mTOR), and NFkB, all of which are linked to ER stress and oxidative stress responses. These

pathways engage in highly redundant crosstalk via cross-reactivity of intracellular signaling mediators and induction of gene transcription, and conspire to integrate multiple stimuli to regulate fundamental aspects of cell metabolism, survival, and death in response to nutrient availability and cell stressors such as hypoxia.

6 As inflammation persists, adipose tissue undergoes fibrotic remodeling, with increased expression of matrix metalloproteases and collagens and increased extracellular matrix turnover. Adipose tissue fibrosis limits adipocyte hypertrophic and lipid storage capacity, accelerating adipocyte stress. Obese collagen VI knockout mice demonstrate increased adipocyte hypertrophic capacity due to decreased fibrosis and are protected from systemic metabolic disease.¹⁹ These observations speak to a critically important role for adipose tissue as a buffer for excess nutrients, metabolites, and metabolic toxins. As obesity progresses, adipose tissue buffering capacity is overwhelmed and cell stress responses, initially confined to adipose tissue, overflow into circulation and cause systemic metabolic disease (Fig. 4-6).

Adipose tissue anatomy, adipose tissue overflow, and the pathogenesis of systemic metabolic disease: Patients with rare congenital and acquired lipodystrophy syndromes characterized by a paucity of adipose tissue suffer from metabolic disease just as in obesity, including insulin resistance, hyperlipidemia, and hepatic steatosis, demonstrating that the absence of adipose tissue is as detrimental as its excess. In lipodystrophy and obesity, adipose tissue nutrient buffering capacity is overwhelmed, and nutrients overflow to other tissues not as well adapted as adipose tissue to manage nutrient excess, inducing systemic metabolic disease.

Adipocytes are present throughout the mammalian body in discrete anatomic depots as well as within every organ and every tissue. Adipose tissue is more than simply a storage depot for lipid; only half the cells in adipose tissue are adipocytes, the remainder comprising the so-called stromovascular cell fraction, which consists of immune leukocytes, fibroblasts, endothelial cells, adipocyte stem cells, and other cell types. Adipose tissue is highly innervated with sympathetic and parasympathetic afferent and efferent fibers, and has important immunoregulatory and endocrine functions. Adipose tissue participates in robust communication with the CNS and all peripheral organs, orchestrating responses to alterations in nutrient availability, systemic health and metabolism, ambient temperature, and a host of other stimuli. Adipose tissue is a central regulator of systemic energy homeostasis.

Hibernating bears accumulate large amounts of adipose tissue without developing inflammation or other cellular stress responses, while in some humans, excess subcutaneous adipose tissue appears to protect against metabolic disease. These examples demonstrate that adipose tissue phenotype is as important as quantity with respect to systemic metabolic state. Adipose tissue may be broadly divided into white and brown phenotypes. White adipose tissue comprises the majority of adipose tissue in humans, is strongly associated with metabolic disease, increases with increasing obesity, and is a primary storage site for lipid. Brown adipose tissue, in contrast, comprises a minority of total adipose tissue in humans, has beneficial effects on metabolism, decreases with increasing obesity and with age, and manifests lower lipid storage capacity. Brown adipocytes engage in higher levels of fatty acid oxidation and thermogenesis via expression of mitochondrial UCPs. White adipose tissue derives from mesodermal stem cells that migrate to sites of canonical depots in humans in early embryonic development and proliferate to form defined depots in late fetal and early neonatal periods. White adipose tissue depots include visceral and subcutaneous, which may be further subdivided into omental, retroperitoneal, and mesenteric visceral adipose tissue (VAT) compartments, and deep and superficial subcutaneous adipose tissue compartments, each with distinct functional characteristics. Brown adipose tissue develops in rodents during gestation from precursor cells that also give rise to myocytes and form defined brown adipose tissue depots prior to birth. Brown adipose tissue in humans is less well understood; while most voluminous in the neonatal period, positron emission tomography scanning demonstrates cervical, supraclavicular, mediastinal, paraspinal, and perirenal brown adipose tissue depots in adult humans as well.²⁰

Figure 4-6. Nutrient excess and cell stress in adipocytes. Nutrient excess is an early signal that induces ER stress and hypertrophy in adipocytes. ER stress is tightly linked to oxidative stress and inflammation, and each of these processes induces and potentiates the others. As hypertrophy progresses, adipocyte diameter expands beyond the diffusion distance of oxygen, leading to cellular hypoxia, which exacerbates cell stress responses, leading to adipocyte apoptosis and necrosis via the unfolded protein response and other advanced cell stress responses. Adipocyte apoptosis and necrosis trigger recruitment of an advanced inflammatory response designed to scavenge dead and dying adipocytes. This inflammatory response is associated with fibrotic tissue remodeling which limits adipocyte hypertrophic and lipid buffering capacity of surviving adipocytes, leading to overflow of lipids, nutrients, metabolites, and inflammatory products from adipose tissue into the systemic circulation.

Recent data suggest that the dichotomy between white adipose tissue and brown adipose tissue is overly simplistic, and that adipocyte phenotype spans a spectrum. An intermediate phenotype, termed “*brite*” (brown-in-white) or “*beige adipocytes*,” is found in white adipose tissue depots in rodents and humans. These cells manifest brown adipocyte functions, and are induced to proliferate by cold stress and β -adrenergic stimuli, suggesting phenotypic plasticity. An important area of research is directed toward understanding the mechanisms that regulate adipocyte phenotype. The recently described protein *irisin* is secreted by skeletal muscle in response to exercise, induces a brown phenotype in adipocytes and improves systemic metabolism when overexpressed in mice.²¹ This finding underscores the importance of interorgan communication in controlling adipose tissue biology and suggests the potential for pharmacologic mediators to manipulate adipocyte phenotype with beneficial effects on systemic metabolism, the so-called “browning” of adipose tissue.

Human adipose tissue accumulation is anatomically heterogeneous. Human obesity may be broadly classified into android and gynecoid phenotypes, defined by excess VAT and subcutaneous adipose tissue, respectively. Excess VAT is strongly associated with metabolic disease; excess subcutaneous adipose tissue, in contrast, is less strongly associated with metabolic disease, and in some studies has been shown to be protective, suggesting a greater lipid buffering capacity. Surgical lipectomy of VAT but not subcutaneous adipose tissue ameliorates murine diabetes.²² In contrast to mice, similar studies of visceral omentectomy in humans demonstrate conflicting results, likely due to more complex human adipose tissue depot anatomy, but excess VAT as measured by waist circumference and imaging techniques nonetheless correlates strongly with metabolic disease. The reasons for the disproportionate effect of VAT on metabolic disease are unclear. While the abdominal location of VAT plays a role, intrinsic differences between visceral and subcutaneous adipose tissues also exist, evidenced by experiments in which transplantation of subcutaneous adipose tissue into a visceral location ameliorates metabolic disease in mice.²³ VAT manifests higher levels of inflammation, lipolysis, β -adrenergic receptor expression, steroid sensitivity, insulin resistance, and adipocyte proliferation and differentiation relative to subcutaneous adipose tissue.

SYSTEMIC METABOLIC DISEASE

Mediators of systemic metabolic disease: In addition to its distinct functional phenotype, VAT also contributes to metabolic disease via its direct anatomic communication with the liver via the portal venous system. *Portal overflow* of free fatty acids, excess nutrients and metabolites, and hormones and cytokines from VAT to the liver is an early step in the progression to systemic metabolic disease. As it progresses, *peripheral overflow* extends beyond the liver to involve all tissues. Adipose tissue overflow affects not only skeletal muscle, vasculature, kidneys, and lungs, but also the CNS; inflammation and ER stress have been documented in the hypothalamus in obesity, and mediate reciprocal effects on adipose tissue and other organ systems via aberrations in CNS efferent outputs that exacerbate obesity and metabolic disease. In essence, adipose tissue dysfunction “metastasizes” as its buffering capacity is

overwhelmed, inducing cell stress responses in all tissues that underlie the pathogenesis of metabolic disease (Fig. 4-7).

Figure 4-7. Adipose tissue overflow, interorgan communication, and systemic metabolic disease. As adipose tissue buffering capacity is overwhelmed, lipids, nutrients, cytokines, and adipokines overflow into the systemic circulation and cause systemic metabolic disease via the same cellular effects that initially unfold in adipocytes. Early overflow occurs via the portal system, which drains visceral adipose tissue venous effluent into the liver, which becomes the first site of systemic metabolic disease and an important secondary site of nutrient buffering via the development of hepatic steatosis. Overflow progresses to involve all peripheral tissues, inducing cell stress and disease in all organ systems. Overflow involves the central nervous system as well, as inflammation and cell stress have been documented in the hypothalamus in obesity, which in turn is thought to disturb peripheral metabolic function via alterations in CNS efferent signaling.

Nutrients and metabolites are central mediators of the systemic effects of adipose tissue overflow. Free fatty acids mediate systemic *lipotoxicity*, a central mechanism of metabolic disease. Free fatty acids trigger inflammation via binding to Toll-like receptors, and also act as ligands for multiple other immunostimulatory and cell stress-inducing receptor families. Lipid metabolites induce cellular insulin resistance, ER stress, and apoptosis. Metabolic products of glucose and fructose, including advanced glycation end products and glucosamines, mediate similar effects. Cytokines and adipokines overflow from adipose tissue as well. $\text{TNF-}\alpha$, a dominant inflammatory cytokine expressed by ATM in obesity, exerts proinflammatory and diabetogenic effects on tissues via diverse mechanisms. Leptin also promotes inflammation and regulates cellular glucose homeostasis. Expression of adiponectin, which attenuates inflammation and has beneficial effects of cellular metabolism, is decreased in obesity, as adipose tissue's cytokine and adipokine balance shifts toward a proinflammatory milieu. Metabolites, adipokines, and cytokines establish in multiple tissues the same cellular stress responses that initially unfold in adipose tissue, including ER stress, oxidative stress, and inflammation. Within target tissues, as in adipose tissue, these processes potentiate one another and exacerbate cell stress, forming the basis for systemic metabolic disease.

7 Portal overflow and liver disease: The liver is one of the first organs to be affected by failure of adipose tissue buffering, as portal overflow induces hepatic steatosis. Hepatic steatosis is the result of an imbalance in the delivery and export of hepatocyte lipid. Sources of hepatic lipid include fats absorbed from the diet and delivered from the gut as chylomicrons, lipids synthesized by hepatocytes via *de novo* lipogenesis, and free fatty acids delivered from VAT via the portal venous system and from subcutaneous adipose tissue via the systemic venous system. Free fatty acids from adipose tissue are a dominant source of hepatic lipid in obesity, constituting over 60% of lipid delivery to the liver.²⁴ Lipids are exported from the liver primarily in the form of very low-density lipoproteins (VLDL). Abnormalities in each of these aspects of hepatic lipid delivery and efflux that contribute to steatosis

have been identified in obese animals and humans, including increased free fatty acid delivery to the liver from increased adipose tissue stores, increased hepatocyte de novo lipogenesis, and decreased VLDL secretion.

As lipid storage capacity is reached, hepatocytes experience ER stress, oxidative stress, and inflammatory responses via similar mechanisms as in adipose tissue, causing steatohepatitis, a histologic entity characterized by Mallory bodies, hepatocyte ballooning, and an inflammatory infiltrate consisting of macrophages (Kupffer cells) and other leukocytes. As in adipose tissue, TNF- α plays a central role in the hepatic inflammatory state, and neutralization of TNF- α ameliorates steatohepatitis in mice and is under study as therapy in humans with promising results.^{25,26} IL-6 and other inflammatory cytokines have also been implicated as mediators of steatohepatitis.

Steatosis is strongly associated with obesity and is present in over 90% of patients with a BMI >40. Up to 30% of these patients will develop steatohepatitis and 10% to 30% of patients with steatohepatitis will develop cirrhosis. Genetics contributes to these risks: ethnic predispositions to steatosis and steatohepatitis exist, with Asians and Hispanics at higher risk than Caucasians or Blacks. Weight loss secondary to diet or bariatric surgery reverses steatosis and halts progression of steatohepatitis in most patients. Few pharmacologic options exist that specifically treat obesity-associated liver disease.

Diabetes: Insulin resistance is a central metabolic response of all cells to stress. ER stress, oxidative stress, and inflammation each induce insulin resistance. Insulin resistance begins in adipose tissue. Free fatty acids are central mediators of cellular insulin resistance. Insulin regulates not only glucose homeostasis in adipocytes, but also lipid metabolism, inhibiting lipolysis and free fatty acid release. Early nutrient excess, with resultant ER stress and oxidative stress, induces insulin resistance in adipocytes, not only impairing adipocyte glucose uptake, but also attenuating insulin's inhibitory effects on lipolysis and thus increasing free fatty acid release by adipocytes. Free fatty acids in turn trigger inflammation via activation of Toll-like receptors on resident adipose tissue inflammatory cells, inducing expression of inflammatory cytokines, including TNF- α . TNF- α plays a central role in the evolution of insulin resistance, regulating the expression and phosphorylation of multiple genes involved in glucose homeostasis, including insulin receptor, insulin receptor substrates, the cell signaling nexus protein Akt, and glucose transporter molecules. TNF- α also promotes lipolysis, further exacerbating insulin resistance and free fatty acid release by adipocytes. While multiple other mediators contribute, these interactions between free fatty acids and TNF provide a cogent example of the vicious cycle established in adipose tissue that contributes to worsening insulin resistance.

As adipose tissue lipid buffering capacity is overwhelmed, free fatty acids overflow into the systemic circulation, resulting in lipotoxicity, which underlies the pathogenesis of insulin resistance in all peripheral tissues. Skeletal muscle, responsible for 60% to 80% of systemic glucose disposal, is a dominant site of systemic insulin resistance. Similar to adipocytes and hepatocytes, skeletal muscle myocytes accumulate lipid and exhibit ER stress, oxidative stress, and inflammation which contribute to insulin resistance via mechanisms described above. Skeletal muscle, like adipose tissue, becomes inflamed, with increased levels of macrophages and diabetogenic inflammatory cytokines. Increased circulating free fatty acids also have important metabolic effects on the liver and skeletal muscle. As lipid delivery to skeletal muscle and liver increases, energy production shifts from glucose utilization to fatty acid oxidation. Increased free fatty acid beta-oxidation is associated with increased gluconeogenesis in the liver and a reduction in glucose utilization in skeletal muscle, exacerbating hyperglycemia. The initial response of pancreatic beta cells to the resultant peripheral insulin resistance is a compensatory increase in insulin secretion, leading to hyperinsulinemia. As disease progresses, lipotoxicity and cell stress responses affect pancreatic beta cells. Beta cell exhaustion ensues, insulin secretion decreases, and insulin resistance progresses to frank diabetes.

Type 2 diabetes is strongly associated with obesity, with risk ratios increasing dramatically with increasing BMI. Like obesity itself, genetics plays an important role: Asian, Black, and Hispanic ethnicities are associated with increased risk and multiple SNPs that correlate with diabetes have been identified. The specific mechanisms by which genetics contribute to increased susceptibility to cellular insulin resistance and lipotoxicity are not yet well understood. Worldwide incidence is rapidly increasing and diabetes represents a dominant emerging health crisis.

The obesity–cancer connection: Obesity is a strong risk factor for cancer. The incidences of almost all types of cancer increase in a dose-dependent manner with increasing BMI, and at elevated BMI >40, risk ratios range from 2 to greater than 6 depending on the type of cancer.²⁷ The mechanisms underlying the association between obesity and cancer are not well defined. At the cellular level, energy homeostasis involves fundamental processes central to carcinogenesis, and signaling pathways activated

by chronic overnutrition promote cell proliferation. Suggesting the potential for cancer therapy based on manipulation of metabolism, epidemiologic data suggest that long-term metformin use is associated with decreased cancer incidence. Chronic inflammation, characteristic of obesity and a well-established risk factor for cancer, activates NFκB and other signaling pathways that potentiate cell proliferation, increase production of reactive oxygen species that may contribute to oncogenic mutation, and induce expression of inflammatory cytokines that act as cell mitogens. Overnutrition in obesity predisposes to a state of chronic anabolism and is associated with increased expression of multiple growth factors that may promote cancer, including insulin, insulin-like growth factor-1, and leptin. Chronic inflammation on a background of chronic anabolism creates an ideal milieu for carcinogenesis. Steroids represent another putative molecular link between obesity and cancer. Steroid metabolism is aberrant in obesity and adipose tissue is a source of estrogen which may promote estrogen-responsive cancers. Finally, adipocytes have been implicated in carcinogenesis, with data demonstrating that peritumor adipose tissue contributes to tumor progression. In addition, adipocyte precursors home from adipose tissue depots to tumors and provide growth factors and metabolic energy substrates that promote tumor growth. The mechanisms by which obesity causes cancer are multiple, and as details are elucidated, metabolism-based therapy for cancer will emerge.

CONCLUSION

Obesity is associated with an increased risk of cardiovascular disease, including hypertension, atherosclerosis, and hyperlipidemia, the result of cell stress responses that afflict vascular tissue. Immune diseases including allergy, atopy, and autoimmune diseases, are increased in the obese, due in part to the above described alterations in immune and inflammatory functions. While mechanical stress due to excess weight is a contributing factor to sleep apnea, osteoarthritis, and gastroesophageal reflux disease, fundamental cell stress mechanisms also contribute, as inflammation has been implicated in these diseases as well. The pan-systemic nature of metabolic disease provides substantial opportunity for developing therapy that will simultaneously treat multiple obesity-related pathologies.

Chapter 5

Wound Healing

Rajiv Chandawarkar and Michael J. Miller

Key Points

- 1 Nonhealing wounds affect about 3 to 6 million people in the United States, with persons 65 years and older accounting for 85% of these events. The annual cost of this problem in the United States is estimated to be as high as \$25 billion for hospital admissions, antibiotics, and local wound care. The development of new data regarding the normal and pathologic wound healing responses both at the cellular levels and the biological markers associated with them will help us develop new strategies to treat these difficult expensive clinical problems.
 - 2 Normal wound healing is achieved through four highly integrated and overlapping biophysiological phases: *hemostasis, inflammation, proliferation, and tissue remodeling or resolution*. Each phase initiates a cascading set of processes critical to the final aim of a healed wound.
 - 3 Wound healing is a complex biological process that consists of hemostasis, inflammation, proliferation, and remodeling. Large numbers of cell types – including neutrophils, macrophages, lymphocytes, keratinocytes, fibroblasts, and endothelial cells – are involved in this process. Multiple factors can cause impaired wound healing by affecting one or more phases of the process and are categorized into local and systemic factors.
 - 4 Clinically the process of wound healing is important to understand from several perspectives. These include: development of precise, least-traumatic surgical technique; the clear understanding of how newer developments in the field of biofilm and anti-infective therapies affect wound management; factors that lead to the formation of chronic versus acute wounds, and importantly, the comorbid conditions that affect wound healing. The role of age, gender, nutrition, obesity, and diabetes are critical factors to incorporate into the therapeutic repertoire.
-

The role of disease states including diabetes, and cancer-related treatments including radiation, chemotherapy and ways to mitigate these factors are as important to assimilate.

1 A fundamental understanding of wound healing is essential to surgical practice. Years of research have yielded extraordinary details of the wound healing process. The complexity can lead the practicing clinician to the conclusion that this topic is perhaps best reserved for the wound specialist. It is critical, however, for the practicing surgeon to have a fundamental understanding of wound healing. Besides the controlled injury that occurs in elective surgery, all invasive surgical procedures cause soft tissue trauma regardless of the circumstances. All aspects of surgical care from patient selection, surgical instruments and technique, and postoperative management are intended to optimize tissue healing and avoid complications. Highly specialized neurosurgical or cardiac procedures can be fraught with complications if sound principles of soft tissue wound healing are overlooked. In addition to surgical procedures, there is the growing problem of people suffering from chronic wounds. Nonhealing wounds affect about 3 to 6 million people in the United States, with persons 65 years and older accounting for 85% of these events. The annual cost of this problem in the United States is estimated to be as high as \$25 billion for hospital admissions, antibiotics, and local wound care.¹ Minimizing wound complications is essential in the current health care environment with an emphasis on quality and safety with publicly reported outcomes such as surgical site infection and readmission rates. For the benefit of the patient and to meet increasingly stringent scrutiny of surgical outcomes by the public, it is incumbent on the surgeon to be more than a technician. Specifically, the surgeon needs to understand how surgery alters tissues and the physiology of healing in order to obtain the best outcomes for their patients. This understanding is essential to allow the surgeon to constantly improve personal technique and quality outcomes. The development of new data regarding the normal and pathologic wound healing responses both at the cellular levels and the biological markers associated with them will help develop new strategies.

NORMAL WOUND HEALING

The series of events associated with wound healing begins at the moment of injury. Although different kinds of tissue (i.e., skin, fat, muscle, bone, nerve, parenchymal organs) have unique responses to injury, each follows a similar process that involves four sequential overlapping periods known as the hemostasis, inflammatory, proliferative, and remodeling phases of wound healing. The process is best understood by considering a full-thickness injury of the skin, dermis, and subcutaneous tissue associated with a simple surgical incision common to every surgical specialty.

2 Normal wound healing is achieved through **four** highly integrated and overlapping biophysiological phases: *hemostasis, inflammation, proliferation, and tissue remodeling or resolution*.² For a wound to heal successfully, as shown in Figure 5-1, all four phases must occur in the proper sequence and time frame (that takes almost 1 year to complete) and continue for a specific duration at an optimal intensity³ (Table 5-1).

Cellular components, the dominant processes as well as biochemical environments that elicit each of the phases are markedly different in their functionality and work in concert to result in a normal healed wound (Fig. 5-2). As shown in Figure 5-3, each phase initiates a cascading set of processes critical to the final aim of a healed wound. In addition, the dominant cytokines for each phase are shown in Figure 5-4.

Figure 5-1. Four phases of wound healing: plotted against “Time” on the X axis, the four phases shown in different colors occur sequentially, and overlap. Overall the total time period for completion is 1 year.

Hemostasis

The first phase of hemostasis begins almost instantaneously after wounding. A scalpel drawn across intact skin injures cells in the epidermis and dermis and separates components of the extracellular matrix (ECM) that support the normal three-dimensional framework of the tissue and preserves the barrier function. The zone of injury is limited to the dimensions of the blade when using a conventional metal scalpel. With electrosurgery, the injury extends some distance into the surrounding tissues depending on the power settings on the device. As the surgeon deepens the incision, the blood vessels in the sub-dermal plexus and deeper in the subcutaneous planes, are cut, and bleeding occurs. The tissue response is mediated by factors from three sources: (1) blood leaking into the wound, (2) proteins stored in the ECM, and (3) locally resident surviving cells.

Table 5-1 Cellular and Biological Events that Frame the Normal Wound Healing Process

Phase	Cellular and Biophysiologic Events
Hemostasis	Vascular constriction Platelet aggregation, degranulation, and fibrin formation (thrombus)
Inflammation	Neutrophil infiltration Monocyte infiltration and differentiation to macrophage Lymphocyte infiltration
Proliferation	1. Re-epithelialization 2. Angiogenesis 3. Collagen synthesis 4. ECM formation
Remodeling	1. Collagen remodeling 2. Vascular maturation and regression

ECM, extracellular matrix.

Circulating factors that initiate the inflammatory phase of healing are platelets, plasma proteins, and leukocytes. Platelets are unnucleated formed elements in the blood produced in the bone marrow by megakaryocytes. The plasma membrane of each platelet contains specific receptors for collagen known as the glycoprotein Ia/IIa complex. The platelet cytoplasm contains granules holding an array of factors important for hemostasis and inflammation. When plasma membrane receptors come into contact with collagen of the ECM (type I) and the basement membrane of the vascular endothelium (Type IV), platelets bind and anchor to the site. Simultaneously, platelet activation occurs and the platelet changes from a rounded amorphous shape to a flattened configuration and discharges the contents of stored cytoplasmic granules in an event known as the platelet release reaction. These bioactive factors serve a dual purpose in hemostasis and wound healing. Hemostasis is promoted by factors that cause strengthened force of platelet binding, accelerated platelet aggregation, vasoconstriction, and activation of the clotting cascade. Platelet anchoring is strengthened by von Willebrand factor (vWF) released by damaged endothelium and activated platelets. Platelet binding is also characterized by rapid vascular constriction and the formation of a stable fibrin clot. Platelets are the main cellular players of the first phase (Fig. 5-5A and Fig. 5-5B). By their collective function, they prevent hemorrhage. Platelet-derived functions that achieve this goal include: adhesion, aggregation, and formation of a procoagulant surface that facilitates the generation of thrombin and results in a fibrin plug. In addition, platelets express and release substances that promote tissue repair and influence processes such as angiogenesis, inflammation, and the immune response. They contain large secretable pools of biologically active proteins, including platelet-derived growth factor (PDGF), transforming growth factor- β (TGF- β), and vascular endothelial growth factor (VEGF) as well as cytokines while newly synthesized active metabolites including proteins such as PF4 and CD40L are also released. Although anucleate, activated platelets possess a spliceosome and can synthesize tissue factor and interleukin-1 β . The binding of secreted proteins within a developing fibrin mesh or to the ECM can create chemotactic gradients favoring the recruitment of stem cells, stimulating cell migration and differentiation, and promoting repair.⁴ The therapeutic use of platelets in a fibrin clot has a positive influence in clinical situations requiring rapid healing. Dental implant surgery, orthopedic surgery, muscle and tendon repair, skin ulcers, hole repair in eye surgery and cardiac surgery are situations where the use of autologous platelets accelerates healing.

Figure 5-2. The dominant cells, physiologic process as well as the temporal distribution of the four phases of wound healing.

Figure 5-3. Flow chart of the phases and the cascading steps that result from each phase.

Figure 5-4. The patterns of cytokines and growth factors within each phase of wound healing.

Figure 5-5. A: Diagrammatic wound healing model. Platelets, the first cells to arrive at the wound are critical to create a clot and establish hemostasis B: Phase 1 – Hemostasis.

The growing platelet plug inside the vessel is stabilized by fibrin polymerized from circulating fibrinogen. The vascular response is mediated by local factors modulated by the systemic control of the sympathetic nervous system. Vasoconstriction, mediated by catecholamines and prostaglandins (thromboxane and PGF_{2a}), normally is limited to the time required to achieve hemostasis. Vasodilation and alteration in capillary permeability soon follow mediated by histamine, prostaglandins (PGE_2 and PGI_2), and VEGF released from resident interstitial mast cells and damaged endothelium. This causes increased blood flow and controlled delivery of fluid, leukocytes, macrophages, and relevant plasma proteins to the wound environment. Platelets release two factors with particular importance for wound healing: PDGF and $\text{TGF-}\beta$. Which in turn stimulate chemotaxis and proliferation of inflammatory cells.

Inflammatory Phase

The second phase of healing involves acute inflammation that begins at the moment of tissue disruption. Inflammatory cells appearing during this phase of healing are polymorphonuclear leukocytes (PMNs) and macrophages. PMNs are first to appear (Fig. 5-6). Their primary role is to clear devitalized tissue, blood clot, foreign material, and bacteria from the wound. PMNs are part of natural host defenses that destroy bacteria by phagocytosis and secreting oxygen free radicals. Migration of PMNs from the intravascular compartment (the lumen) to the ECM and to the wound site is controlled by several biochemical agents including selectins, cytokines, and integrins that act in series to activate, tether, and facilitate extravascular escape (Fig. 5-7). PMNs work in concert with the immune system antibodies. Their numbers and persistence depend on the initial wound conditions. A clean surgical wound performed with atraumatic tissue handling will have low PMN activity, whereas a poorly performed surgical incision or a traumatic wound may be characterized by a large amount of debris and require

prolonged participation of PMNs to set the stage for appearance of macrophages, the most important cellular mediator of the inflammatory phase of wound healing.

Figure 5-6. Phase 2 – Inflammation.

Macrophages appear in large numbers within 48 hours of wounding and play a central role in the inflammatory phase. They are derived from circulating monocytes or resident interstitial cells that migrate into the wound from adjacent tissues. Macrophages are multifunctional (Fig. 5-8) and complete the cleanup activities initiated by the PMNs by phagocytizing remaining wound debris. Most importantly, they secrete a vast array of cytokines and growth factors, which function in a rapidly amplifying process that affects all aspects of healing during the inflammatory phase. These factors induce recruitment and activation of additional macrophages, angiogenesis, proliferation of fibroblasts, and ECM production. Matrix production is accelerated as the inflammatory phase of healing transitions into the next phase of healing, the proliferative phase.

Proliferative Phase

The defining characteristic of the proliferative phase of healing is ECM production (Fig. 5-9). The phases of wound healing are not discrete. While the inflammatory phase is still most active, the proliferative phase begins with formation of a provisional ECM composed of fibrin and fibronectin precipitated from blood extravasated into the wound at the time of the initial injury. The provisional matrix is a protein scaffold that stabilizes the wound edges and provides a framework for migration of PMNs, macrophages, fibroblasts, and other cells into the wound from surrounding tissues. As the inflammatory phase slows the proliferative phase begins and becomes dominant. Fibroblasts replace macrophages as the most numerous cell type. Like macrophages, fibroblasts are multifunctional. They are responsible for new tissue formation, collagen production, and the laying down of the ECM (Fig. 5-9). Angiogenesis occurs simultaneously as new capillaries form and blood vessels penetrate the provisional matrix sprouting from vessels of the surrounding uninjured tissues. The processes that actually coordinate formation of ECM and new tissue with angiogenesis are not well defined. Signaling pathways that stimulate new tissue formation involve the role of low oxygen tension that increases the expression of “hypoxia-inducible factor” (HIF) by vascular endothelial cells. HIF in turn binds to specific sequences of DNA that regulate the expression of VEGF thus stimulating angiogenesis. This also has a negative feedback loop – increased formation of new blood vessels normalizes the oxygen tension. In response, oxygen binds to HIF and blocks its activity resulting in decreased synthesis of VEGF. Epidermal growth factor and TGF α produced by activated wound macrophages, platelets, and keratinocytes play an important role at the creation of a robust scaffold.

Figure 5-7. The biochemical factors that elicit migration of cells from intravascular compartment into the wound site.

Figure 5-8. Macrophage functions.

Epidermal cells migrate over the scaffold and only after the epithelial bridge is completed, enzymes are released to dissolve the attachment at the base of the overlying scab that falls off. In response to the growing need for oxygen and nutrients at the site of healing, the wound microenvironment stimulates the release of factors needed to bring in a new blood supply (low pH, reduced oxygen tension, and increased lactate). This process – angiogenesis or neovascularization is stimulated by VEGF, basic fibroblast growth factor (bFGF), and TGF β . These factors are secreted by several cell types including vascular endothelial cells, epidermal cells, fibroblasts, and macrophages.

As the proliferative phase progresses the predominant cell in the wound site is the fibroblast. This multifunctional cell of mesenchymal origin mainly produces and deposits the new matrix for structural integrity at the level of the wound bed (Fig. 5-9B). ECM production is the defining feature of the proliferative phase. The ECM is primarily collagen. At least 23 individual types of collagen have been identified – type I is present mostly in scar tissues.⁵ Fibroblasts produce collagen via their attachment to the cables of the provisional fibrin matrix.⁶ After transcription and processing of the collagen messenger ribonucleic acid, it is attached to polyribosomes on the endoplasmic reticulum where the new collagen chains are produced. During this process, there is an important step involving hydroxylation of proline and lysine residues.⁷ The collagen molecule transforms itself into the classical triple helical structure and thereafter its nascent chains are modified through glycosylation⁸; this procollagen molecule is released into the extracellular space.⁹ The hydroxyproline in collagen gives the molecule its stable helical conformation.¹⁰ Whereas fully hydroxylated collagen has a higher stability, unhydroxylated forms are fragile, similar to collagen produced under anaerobic disease conditions or vitamin C-deficient states (scurvy), wherein the collagen undergoes denaturation easily and can break.

Figure 5-9. A: Phase 3 – Proliferation. Vast array of cells are recruited into the wound bed and carry out diverse functions including proliferation and deposition of ECM. B: Fibroblast functions.

Figure 5-10. Phase 4 – Remodeling and Maturation.

Finally, collagen released into the extracellular space undergoes further processing by cleavage of the procollagen N- and C-terminal peptides. In the extracellular spaces, an important enzyme, lysyl oxidase, acts on the collagen to form stable cross-links. As the collagen matures and becomes older, more and more of these intramolecular and intermolecular cross-links are placed in the molecules. This important cross-linking step gives collagen its strength and stability over time.¹¹

Remodeling Phase

The remodeling phase is characterized by continued synthesis and degradation of the ECM components trying to establish a new equilibrium – and the formation of an organized scar (Fig. 5-10). Collagen degradation occurs¹² via the action of specific collagenases that are secreted by various cells: fibroblasts, neutrophils, and macrophages each of which can cleave the collagen molecule at differing but specific locations on all three chains, and break it down to characteristic three-quarter and one-quarter pieces. These collagen fragments undergo further denaturation and digestion by other proteases. Several molecules including TGF play a major role in the remodeling phase. TGF- β -induced intracellular signaling acts via a set of proteins called the SMAD proteins, which act as direct links between the cell surface and the nucleus. The recent development of several SMAD pathway specific knockout mice and transgenic animals has confirmed the pivotal nature of the SMAD pathway in fibrogenesis and tumorigenesis. Still, several difficulties remain before the TGF- β /SMAD pathway can be efficiently targeted in situations such as tissue fibrosis or impaired wound healing. In particular, the precise spatiotemporal role of each TGF- β /SMAD pathway component during the development of excessive

ECM deposition leading to tissue fibrosis remains to be ascertained.

As the scar matures, late remodeling occurs (that takes up to 1 year); the scar contracts and thins out (Fig. 5-11).

CLINICAL APPLICATIONS

Surgical Technique

The surgeon equipped with the knowledge of the fundamentals of wound healing is prepared to insightfully minimize risks of wound healing complications while performing a surgical procedure from start to finish. The stage is set for healing from the moment the incision is made. The skin and dermis should be incised perpendicularly to the plane of the surface. Attention to this principle is particularly important when making an incision on a curved surface. Electrosurgical currents should be used set on the lowest power settings that accomplish hemostasis. The deep tissues should be handled as atraumatically as possible. The incision is carried down through deeper layers ensuring that each new incision is accurately placed in the same line as the previous one. This avoids a saw tooth surface with devitalized sections. Proper tissue handling techniques in the subcutaneous fat and adjacent soft tissue are based on well-established wound healing principles, which minimize the risk of infection, seroma, delayed healing, unnecessary scarring, and other postoperative wound complications. For traumatic wounds, the first step in treatment is to convert them into controlled surgical wounds by thoughtful debridement and tissue repair. Treating traumatic wounds minimizing the risk of postoperative wound complications requires mindfulness of wound healing principles in all of these clinical circumstances. This is true regardless whether performing repair of a simple laceration or the most complex specialized procedure. Controlling the degree of injury leads to improved outcomes with fewer complications related to a failure in the wound healing process. An awareness of the wound healing process informs proper surgical technique. A clear understanding of wound healing allows the surgeon to advance in technical skill and achieve continuously improving outcomes throughout a professional career.

Figure 5-11. Contraction of scar – This process occurs over the course of 1 year.

Figure 5-12. Effects of biofilm on wound healing.

Elective surgery creates controlled tissue injury. Minimizing tissue injury forms the basis of proper surgical technique. Trauma injures tissues in an uncontrolled fashion. Wounds can occur under special conditions such as pressure, physiologic impairment (e.g., diabetes) that create traumatic tissue damage in an uncontrolled injury. Finally, there are wounds that occur under specialized circumstances such as radiotherapy in cancer treatment.

Biofilm

Biofilm comprises a colony of microorganisms enveloped with a matrix of extracellular polymers. Estimated biofilm-associated infections costs >\$1 billion annually. Both chronic and acute dermal wounds are susceptible to the formation and propagation of biofilm. Covered in other chapters of this book, biofilm is relevant to wound healing due to the several inhibitory effects on healing processes (Fig. 5-12).

Table 5-2 Comparison of Acute and Chronic Wounds

	Acute	Chronic
Present for	4–6 weeks	6 weeks, usually months/years
Management	Minimal needs ■ Debride ■ Dressings ■ Drugs (antimicrobials usually suffice)	Complex coordinated wound care ■ Treat ROOT CAUSE ■ Wound care ■ Surgery ■ Adjunctive care
Types	Surgical trauma Trauma Bites Uncomplicated burns	Neuropathic Diabetic Vascular Pressure sores

Chronic Versus Acute wounds

Wounds heal within a reasonable time of 4 to 6 week. Those that do not are termed chronic. As shown in Table 5-2, a variety of factors and disease conditions impair wound healing and result in chronic nonhealing wounds. Reasons that lead to chronicity instead of normal healing, are complex – but the salient points are defined in Figure 5-13. The most important concept is a persistent proinflammatory condition that paradoxically leads to increased degradation of matrix proteins, and an unstable wound that is recalcitrant to healing.

Comorbid Conditions that Influence Wound Healing

3 Wound healing is a complex biological process that consists of hemostasis, inflammation, proliferation, and remodeling. Large numbers of cell types – including neutrophils, macrophages, lymphocytes, keratinocytes, fibroblasts, and endothelial cells – are involved in this process. Multiple factors can cause impaired wound healing by affecting one or more phases of the process and are categorized into local and systemic factors (Table 5-3). The influences of these factors are not mutually

exclusive.¹³ Single or multiple factors may play a role in any one or more individual phases, contributing to the overall outcome of the healing process (Fig. 5-14).

Advanced Age and Gender

The elderly population (people over 60 years of age) is growing faster than any other age group (World Health Organization [WHO, www.who.int/topics/ageing]), and increased age is a major risk factor for impaired wound healing. Many clinical and animal studies at the cellular and molecular level have examined age-related changes and delays in wound healing. It is commonly recognized that, in healthy older adults, the effect of aging causes a temporal delay in wound healing, but not an actual impairment in terms of the quality of healing.¹³ Delayed wound healing in the aged is associated with an altered inflammatory response, such as delayed T-cell infiltration into the wound area with alterations in chemokine production and reduced macrophage phagocytic capacity.¹⁴ Overall, there are global differences in wound healing between young and aged individuals. A review of the age-related changes in healing capacity demonstrates that every phase of healing undergoes characteristic age-related changes, including enhanced platelet aggregation, increased secretion of inflammatory mediators, delayed infiltration of macrophages and lymphocytes, impaired macrophage function, decreased secretion of growth factors, delayed re-epithelialization, delayed angiogenesis and collagen deposition, reduced collagen turnover and remodeling, and decreased wound strength.

Table 5-3 Factors that Affect Wound Healing

Local Factors	Systemic Factors
■ Tissue hypoxia ■ Pressure ■ Tissue edema ■ Necrotic material ■ Infection ■ Contamination from incontinence ■ Dessication ■ Maceration	■ Senescence ■ Smoking ■ Stress ■ Comorbidity ■ Immune compromise ■ Malnourishment ■ Obesity ■ Diabetes, anemia

Figure 5-13. Comparison of cellular mechanisms in normal and poor wound healing.

Sex hormones play a role in age-related wound healing deficits. Compared with aged females, aged males have been shown to have delayed healing of acute wounds. A partial explanation for this is that the female estrogens (estrone and 17β-estradiol), male androgens (testosterone and 5α-dihydrotestosterone, DHT), and their steroid precursor dehydroepiandrosterone (DHEA) appear to have significant effects on the wound healing process.¹⁵ It was recently found that the differences in gene expression between elderly male and young human wounds are almost exclusively estrogen regulated.¹⁶ Estrogen affects wound healing by regulating a variety of genes associated with regeneration, matrix production, protease inhibition, epidermal function, and genes primarily associated with inflammation.¹⁷ Studies indicate that estrogen can improve the age-related impairment in healing in both men and women, while androgens regulate cutaneous wound healing negatively.

Figure 5-14. Mechanisms that elicit the effects of comorbid conditions on wound healing.

Several treatments to reduce the age-related impairment of healing have been studied. Interestingly, exercise has been reported to improve cutaneous wound healing in older adults as well as aged mice, and the improvement is associated with decreased levels of proinflammatory cytokines in the wound tissue. Improved healing response may also be due to an exercise-induced anti-inflammatory response in the wound.¹⁸

Nutrition

Malnutrition or specific nutrient deficiencies can have a profound impact on wound healing after trauma and surgery. Patients with chronic or nonhealing wounds and experiencing nutrition deficiency often require special nutrients. Energy, carbohydrates, proteins, fat, vitamins, and mineral metabolism all can affect the healing process.¹⁹

Carbohydrates, Proteins, and Amino Acids. Together with fats, carbohydrates are the primary source of energy in the wound healing process. Glucose is the major source of fuel used to create the cellular ATP that provides energy for angiogenesis and deposition of the new tissues.²⁰ The use of glucose as a source for ATP synthesis is essential in preventing the depletion of other amino acid and protein substrates.

Protein is one of the most important nutrient factors affecting wound healing. A deficiency of protein can impair capillary formation, fibroblast proliferation, proteoglycan synthesis, collagen synthesis, and wound remodeling. A deficiency of protein also affects the immune system, with resultant decreased leukocyte phagocytosis and increased susceptibility to infection. Collagen is the major protein component of connective tissue and is composed primarily of glycine, proline, and hydroxyproline. Collagen synthesis requires hydroxylation of lysine and proline, and cofactors such as ferrous iron and vitamin C. Impaired wound healing results from deficiencies in any of these cofactors.²¹

Arginine is a semiessential amino acid that is required during periods of maximal growth, severe stress, and injury. Arginine has many effects in the body, including modulation of immune function, wound healing, hormone secretion, vascular tone, and endothelial function. Arginine is also a precursor to proline, and, as such, sufficient arginine levels are needed to support collagen deposition, angiogenesis, and wound contraction. Arginine improves immune function, and stimulates wound healing in healthy and ill individuals.²² Under psychological stress situations, the metabolic demand for arginine increases, and its supplementation has been shown to be an effective adjuvant therapy in wound healing.

Glutamine is the most abundant amino acid in plasma and is a major source of metabolic energy for rapidly proliferating cells such as fibroblasts, lymphocytes, epithelial cells, and macrophages. Glutamine improves nitrogen balance and diminishes immunosuppression and plays a crucial role in stimulating the early inflammatory phase of wound healing. Major surgery, trauma, and sepsis require supplementation of glutamine. Oral glutamine supplementation has been shown to improve wound breaking strength and

to increase levels of mature collagen.²³

Fatty Acids

Lipids are used as nutritional support for surgical or critically ill patients to help meet energy demands and provide essential building blocks for wound healing and tissue repair. Polyunsaturated fatty acids (PUFAs), consist mainly of two families, n-6 (omega-6, found in soybean oil) and n-3 (omega-3, found in fish oil). Although fish oil has been widely touted, effects of omega-3 fatty acids on wound healing are not conclusive. They have been reported to affect proinflammatory cytokine production, cell metabolism, gene expression, and angiogenesis in wound sites.²⁴

Vitamins, Micronutrients, and Trace Elements

Vitamins C (L-ascorbic acid), A (retinol), and E (tocopherol) show potent antioxidant and anti-inflammatory effects. Vitamin C has many roles in wound healing, and a deficiency in this vitamin has multiple effects on tissue repair. Vitamin C deficiencies result in impaired healing, and have been linked to decreased collagen synthesis and fibroblast proliferation, decreased angiogenesis, and increased capillary fragility. Also, vitamin C deficiency leads to an impaired immune response and increased susceptibility to wound infection. Similarly, vitamin A deficiency leads to impaired wound healing. The biological properties of vitamin A include antioxidant activity, increased fibroblast proliferation, modulation of cellular differentiation and proliferation, increased collagen and hyaluronate synthesis, and decreased MMP-mediated ECM degradation.²⁵

Vitamin E, an antioxidant, maintains and stabilizes cellular membrane integrity by providing protection against destruction by oxidation. Vitamin E also has anti-inflammatory properties and has been suggested to have a role in decreasing excess scar formation in chronic wounds. Animal experiments have indicated that vitamin E supplementation is beneficial to wound healing, and topical vitamin E has been widely promoted as an antiscarring agent. However, clinical studies have not yet proved a role for topical vitamin E treatment in improving healing outcomes.²⁶

Several micronutrients have been shown to be important for optimal repair. Magnesium functions as a cofactor for many enzymes involved in protein and collagen synthesis, while copper is a required cofactor for cytochrome oxidase, for cytosolic antioxidant superoxide dismutase, and for the optimal cross-linking of collagen. Zinc is a cofactor for both RNA and DNA polymerase, and a zinc deficiency causes a significant impairment in wound healing. Iron is required for the hydroxylation of proline and lysine, and, as a result, severe iron deficiency can result in impaired collagen production.²⁷ As indicated above, the nutritional needs of the wound are complex, suggesting that composite nutrition support would benefit both acute and chronic wound healing. A recent clinical research study examined the effects of a high-energy, protein-enriched supplement containing arginine, vitamin C, vitamin E, and zinc on chronic pressure ulcers and indicated that this high-energy and nutrition-enriched supplement improved overall healing of the pressure ulcer.²⁸ In summary, proteins, carbohydrates, arginine, glutamine, PUFAs, vitamin A, vitamin C, vitamin E, magnesium, copper, zinc, and iron play a significant role in wound healing, and their deficiencies affect wound healing. Additional studies will be needed to fully understand how nutrition affects the healing response.

Obesity

The prevalence of obesity continues to increase among adults, children, and adolescents in the United States, with more than 30% of adults and 15% of children and adolescents classified as obese in a recent survey.²⁹ Obesity is well known to increase the risk of many diseases and health conditions, which include coronary heart disease, type 2 diabetes, cancer, hypertension, dyslipidemia, stroke, sleep apnea, respiratory problems, and impaired wound healing. Obese individuals frequently face wound complications, including skin wound infection, dehiscence, hematoma and seroma formation, pressure ulcers, and venous ulcers.³⁰ An increased frequency of wound complications has been reported for obese individuals undergoing both bariatric and nonbariatric operations.³¹ In particular, a higher rate of surgical site infection occurs in obese patients. Many of these complications may be the result of a relative hypoperfusion and ischemia that occurs in subcutaneous adipose tissue. This situation may be caused by a decreased delivery of antibiotics as well. In surgical wounds, the increased tension on the wound edges that is frequently seen in obese patients also contributes to wound dehiscence. Wound tension increases tissue pressure, reducing microperfusion and the availability of oxygen to the wound.³²

Figure 5-15. Cellular mechanisms that impair healing of the diabetic wound.

The increase in pressure ulcers or pressure-related injuries in obese individuals is also influenced by hypovascularity, since poor perfusion makes tissue more susceptible to this type of injury. In addition, the difficulty or inability of obese individuals to reposition themselves further increases the risk of pressure-related injuries. Moreover, skin folds harbor microorganisms that thrive in moist areas and contribute to infection and tissue breakdown. The friction caused by skin-on-skin contact invites ulceration. Together, these factors predispose obese individuals to the development of impaired wound healing.

In addition to local conditions, systemic factors also play an important role in impaired wound healing and wound complications in obese patients. Obesity can be connected to stress, anxiety, and depression, all situations that can cause an impaired immune response.

The function of adipose tissue used to be considered as primarily caloric storage. However, more recent findings have documented that adipose tissue secretes a large variety of bioactive substances that are collectively named adipokines. Both adipocytes as well as resident macrophages in adipose tissue are known to produce bioactive molecules including cytokines, chemokines, and hormone-like factors such as leptin, adiponectin, and resistin. Adipokines have a profound impact on the immune and inflammatory response.³³ The negative influence of adipokines on the systemic immune response seems likely to influence the healing process, although direct proof for this is lacking. Impaired peripheral blood mononuclear cell function, decreased lymphocyte proliferation, and altered peripheral cytokine levels have been reported in obesity. Importantly, many of the obesity-related changes in peripheral immune function are improved by weight loss.³⁴

Diabetes Mellitus

Diabetes affects hundreds of millions of people worldwide. Diabetic individuals exhibit a documented impairment in the healing of acute wounds. Moreover, this population is prone to develop chronic nonhealing diabetic foot ulcers (DFUs), which are estimated to occur in 15% of all persons with diabetes. DFUs are a serious complication of diabetes, and precede 84% of all diabetes-related lower leg amputations.³⁵ The impaired healing of both DFUs and acute cutaneous wounds in persons with diabetes involves multiple complex pathophysiological mechanisms (Fig. 5-15). DFUs, like venous stasis disease and pressure-related chronic nonhealing wounds, are always accompanied by hypoxia.³⁶ A situation of prolonged hypoxia, which may be derived from both insufficient perfusion and insufficient angiogenesis, is detrimental for wound healing. Hypoxia can amplify the early inflammatory response, thereby prolonging injury by increasing the levels of oxygen radicals.³⁷ Hyperglycemia can also add to the oxidative stress when the production of reactive oxygen species exceeds the antioxidant capacity.³⁸ The formation of advanced glycation end products under hyperglycemia and the interaction with their receptors are associated with impaired wound healing in diabetic mice as well.³⁹ High levels of metalloproteases (MMP) are a feature of DFUs, and the MMP levels in chronic wound fluid are almost 60 times higher than those in acute wounds. This increased protease activity supports tissue destruction and inhibits normal repair processes.⁴⁰

Several dysregulated cellular functions are involved in diabetic wounds, such as defective T-cell immunity, defects in leukocyte chemotaxis, phagocytosis, and bactericidal capacity, and dysfunction of fibroblasts and epidermal cells. These defects are responsible for inadequate bacterial clearance and delayed or impaired repair in individuals with diabetes.⁴¹

As mentioned above, hypoxia contributes to the compromised healing of DFUs, and diabetic wounds exhibit inadequate angiogenesis. Several studies that have investigated the mechanisms behind the decreased restoration of vasculature in diabetic wounds have implied that endothelial progenitor cell

mobilization and homing are impaired, and that the level of VEGF, the primary proangiogenic factor in wounds, is decreased in the diabetic state.⁴² Stem-cell-based therapies aimed at inducing endothelial progenitor cells or bone marrow-derived multipotent stem cells have shown a promising outcome in diabetic nonhealing wounds, both in animals and in clinical trials.⁴³ In animal studies, therapeutic restoration of VEGF has been shown to improve repair outcomes significantly.⁴⁴

The neuropathy that occurs in diabetic individuals probably also contributes to impaired wound healing. Neuropeptides such as nerve growth factor, substance P, and calcitonin gene-related peptide are relevant to wound healing, because they promote cell chemotaxis, induce growth factor production, and stimulate the proliferation of cells. A decrease in neuropeptides has been associated with DFU formation. In addition, sensory nerves play a role in modulating immune defense mechanisms, with denervated skin exhibiting reduced leukocyte infiltration.⁴⁵

In summary, the impaired healing that occurs in individuals with diabetes involves hypoxia, dysfunction in fibroblasts and epidermal cells, impaired angiogenesis and neovascularization, high levels of MMP, damage from reactive oxygen species and advanced glycation end products, decreased host immune resistance, and neuropathy.

Medications and Dietary Supplements

Glucocorticoid Steroids. Systemic glucocorticoids, which are frequently used as anti-inflammatory agents, are well known to inhibit wound repair via global anti-inflammatory effects and suppression of cellular wound responses, including fibroblast proliferation and collagen synthesis. Systemic steroids cause wounds to heal with incomplete granulation tissue and reduced wound contraction.⁴⁶ Glucocorticoids also inhibit production of HIF-1, a key transcriptional factor in healing wounds.⁴⁷ Beyond effects on repair itself, systemic corticosteroids may increase the risk of wound infection. While systemic corticosteroids inhibit wound repair, topical application produces quite different effects. Topical low-dosage corticosteroid treatment of chronic wounds has been found to accelerate wound healing, reduce pain and exudate, and suppress hypergranulation tissue formation in 79% of cases. While these positive effects are striking, careful monitoring is necessary to avoid a potential increased risk of infection with prolonged use.⁴⁸

Nonsteroidal Anti-Inflammatory Drugs. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen are widely used for the treatment of inflammation and rheumatoid arthritis and for pain management. Low-dosage aspirin, due to its antiplatelet function, is commonly used as a preventive therapeutic for cardiovascular disease, but not as an anti-inflammatory drug.⁴⁹ There are few data to suggest that short-term NSAIDs have a negative impact on healing. However, the question of whether long-term NSAIDs interfere with wound healing remains open. In animal models, systemic use of ibuprofen has demonstrated an antiproliferative effect on wound healing, resulting in decreased numbers of fibroblasts, weakened breaking strength, reduced wound contraction, delayed epithelialization,⁵⁰ and impaired angiogenesis. The effects of low-dose aspirin on healing are not completely clear. Clinical recommendations suggest that, to avoid antiplatelet effects, individuals should discontinue NSAIDs for a time period equal to 4 to 5 times the half-life of drugs before surgery. Thus, the majority of surgical patients do not have significant NSAID activity at the time of wound repair. The exception may be those cardiac patients who must be maintained on low-dose aspirin due to severe risk of cardiovascular events. In terms of the topical application of NSAIDs on the surfaces of chronic wounds, the local use of ibuprofen foam provides moist wound healing, reduces persistent and temporary wound pain, and benefits chronic venous leg ulcer healing.

Peripheral Vascular Disease

Total disease prevalence based on objective testing has been evaluated in several epidemiologic studies and is in the range of 3% to 10%, increasing to 15% to 20% in persons over 70 years.⁵¹ Peripheral vascular disease (PVD) is an independent risk factor for subsequent ulceration and limb loss in diabetes. It is present in 50% of patients with diabetic foot ulcer (DFU), a proportion that may be increasing. Those with DFU and peripheral arterial disease (PAD) are less likely to heal and more likely to require amputation compared to patients without PAD. It is therefore essential that PVD is identified in all patients with diabetes.

Patients with PVD commonly suffer from chronic toe and foot sores, cramping leg muscles when walking or numbness, weakness or heaviness in the muscles. Other PVD symptoms include:

- Numbness in the extremities
- Weakness and atrophy of calf muscles

- A feeling of coldness in legs or feet
- Changes in the color of the feet: feet will turn pale when elevated and turn dusky red when in the dependent position
- Hair loss over the dorsum of the feet, thickening toenails
- Painful ulcers and/or gangrene in tissue, typically in the toes

Pathophysiology: The etiology of ulceration in diabetic patients with PVD is multifactorial distal polyneuropathy (motor, sensory, and autonomic), abnormal foot anatomy, functional changes in the microcirculation in the presence of PVD, lead to abnormal loading or trauma of the poorly perfused painless neuropathic foot. Infection in the foot exponentially increases the demand for oxygen, which in PVD is unmet. Healing is impaired also due to impaired humoral immunity and abnormal inflammatory responses.⁵²

Traditional wound care algorithms include aggressive detection of PAD and treatment with revascularization for all patients with PVD and lower extremity wounds – in order to prevent limb amputation. The Transatlantic Inter-Society Consensus (TASCII) criteria for critical limb ischemia is a commonly used method for revascularization. When the TcPO₂ is > 30 mm Hg, the ankle-brachial index (ABI) and the TASC II definition of critical limb ischemia predict wound healing and should be key factors in considering conservative therapy. New strategies are being developed to diagnose PVD in patients with diabetes, referring those presenting with a new foot ulcer to a multidisciplinary team, so that appropriate interventions help preserve the limb.

Stress

Stress has a great impact on human health and social behavior. Many diseases – such as cardiovascular disease, cancer, compromised wound healing, and diabetes – are associated with stress. Numerous studies have confirmed that stress-induced disruption of neuroendocrine immune equilibrium is consequential to health.⁵³ The pathophysiology of stress results in the deregulation of the immune system, mediated primarily through the hypothalamic–pituitary–adrenal and sympathetic–adrenal medullary axes or sympathetic nervous system.⁵⁴

Studies in both humans and animals have demonstrated that psychological stress causes a substantial delay in wound healing.⁵⁵ Caregivers of persons with Alzheimer's and students undergoing academic stress during examinations demonstrated delayed wound healing.⁵⁶ The hypothalamic – pituitary–adrenal and the sympathetic–adrenal medullary axes regulate the release of pituitary and adrenal hormones. These hormones include the adrenocorticotrophic hormones, cortisol and prolactin, and catecholamines (epinephrine and norepinephrine). Stress upregulates glucocorticoids and reduces the levels of the pro-inflammatory cytokines IL-1 β , IL-6, and TNF- α at the wound site. Stress also reduces the expression of IL-1 α and IL-8 at wound sites – both chemoattractants that are necessary for the initial inflammatory phase of wound healing.⁵⁷ Furthermore, glucocorticoids influence immune cells by suppressing differentiation and proliferation, regulating gene transcription, and reducing expression of cell adhesion molecules that are involved in immune cell trafficking.⁵⁸ Cortisol functions as an anti-inflammatory agent and modulates the Th1-mediated immune responses that are essential for the initial phase of healing. Thus, psychological stress impairs normal cell-mediated immunity at the wound site, causing a significant delay in the healing process.⁵⁹

Stressors can lead to negative emotional states, such as anxiety and depression, which may in turn have an impact on physiologic processes and/or behavioral patterns that influence health outcomes. In addition to the direct influences of anxiety and depression on endocrine and immune function, stressed individuals are more likely to have unhealthy habits, which include poor sleep patterns, inadequate nutrition, less exercise, and a greater propensity for abuse of alcohol, cigarettes, and other drugs. All of these factors may come into play in negatively modulating the healing response.

Cigarette Smoking

It is well known that smoking increases the risk of heart and vascular disease, stroke, chronic lung disease, and many kinds of cancers. Similarly, the negative effects of smoking on wound healing outcomes have been known for a long time.⁶⁰ Postoperatively, patients who smoke show a delay in wound healing and an increase in a variety of complications such as infection, wound rupture, anastomotic leakage, wound and flap necrosis, epidermolysis, and a decrease in the tensile strength of wounds.⁶¹ In the realm of oral surgery, impaired healing in smokers has been noticed both in routine oral surgery and in the placement of dental implants.⁶² Cosmetic outcomes also appear to be worse in smokers, and plastic and reconstructive surgeons are often reluctant to perform cosmetic surgeries on

individuals who refuse to quit smoking.⁶³ Approximately 4000 substances in tobacco smoke have been identified, and some have been shown to have a negative impact on healing.⁶⁴ Most studies have focused on the effects of nicotine, carbon monoxide, and hydrogen cyanide from smoke. Nicotine interferes with oxygen supply by inducing tissue ischemia, since nicotine can cause decreased tissue blood flow via vasoconstrictive effects.⁶⁵ Nicotine stimulates sympathetic nervous activity, resulting in the release of epinephrine, which causes peripheral vasoconstriction and decreased tissue blood perfusion. Nicotine also increases blood viscosity caused by decreasing fibrinolytic activity and augmentation of platelet adhesiveness. In addition to the effects of nicotine, carbon monoxide in cigarette smoke also causes tissue hypoxia. Carbon monoxide binds to hemoglobin with an affinity 200 times greater than that of oxygen, resulting in a decreased fraction of oxygenated hemoglobin in the bloodstream. Hydrogen cyanide, another well-studied component of cigarette smoke, impairs cellular oxygen metabolism, leading to compromised oxygen consumption in the tissues. Beyond these direct tissue effects, smoking increases the individual's risk for atherosclerosis and chronic obstructive pulmonary disease, two conditions that might also lower tissue oxygen tension.⁶⁶

Several cell types and processes that are important to healing have been shown to be adversely affected by tobacco smoke. In the inflammatory phase, smoking causes impaired white blood cell migration, resulting in lower numbers of monocytes and macrophages in the wound site, and reduces neutrophil bactericidal activity. Lymphocyte function, cytotoxicity of natural killer cells, and production of IL-1 are all depressed, and macrophage sensing of gram-negative bacteria is inhibited.⁶⁷ These effects result in poor wound healing and an increased risk of opportunistic wound infection.

During the proliferative phase of wound healing, exposure to smoke yields decreased fibroblast migration and proliferation, reduced wound contraction, hindered epithelial regeneration, decreased ECM production, and upset in the balance of proteases.⁶⁸

Pharmacologically, the influence of smoking on wound healing is complicated, and neither nicotine alone nor any other single component can explain all of the effects of smoking on wounds. What is certain is that smoking cessation leads to improved repair and reduces wound infection.⁶⁹ For surgery patients who find it difficult to forego smoking, the use of a transdermal patch during the preoperative period might be beneficial. A study has shown that the use of a transdermal nicotine patch as a nicotine replacement for smoking cessation therapy can increase type I collagen synthesis in wounds.⁷⁰ Despite the overall negative effects of smoking, some recent studies have suggested that low doses of nicotine enhance angiogenesis and actually improve healing.⁷¹

Alcohol and Substance Abuse

Clinical evidence and animal experiments have shown that exposure to alcohol impairs wound healing and increases the incidence of infection.⁷² The effect of alcohol on repair is quite clinically relevant, since over half of all emergency room trauma cases involve either acute or chronic alcohol exposure. Alcohol exposure diminishes host resistance, and ethanol intoxication at the time of injury is a risk factor for increased susceptibility to infection in the wound.⁷³ Studies have demonstrated profound effects of alcohol on host-defense mechanisms, although the precise effects are dependent upon the pattern of alcohol exposure (i.e., chronic vs. acute alcohol exposure, amount consumed, duration of consumption, time from alcohol exposure, and alcohol withdrawal). A recent review on alcohol-induced alterations on host defense after traumatic injury suggested that, in general, short-term acute alcohol exposure results in suppressed pro-inflammatory cytokine release in response to an inflammatory challenge. The higher rate of postinjury infection correlates with decreased neutrophil recruitment and phagocytic function in acute alcohol exposure.⁷⁴

Beyond the increased incidence of infection, exposure to ethanol also seems to influence the proliferative phase of healing. In murine models, exposure to a single dose of alcohol that caused a blood alcohol level of 100 mg/dL (just above the legal limit in most states in the United States) perturbed re-epithelialization, angiogenesis, collagen production, and wound closure.⁷⁵ The most significant impairment seems to be in wound angiogenesis, which is reduced by up to 61% following a single ethanol exposure. This decrease in angiogenic capacity involves both decreased expression of VEGF receptors and reduced nuclear expression of HIF-1 α in endothelial cells.⁷⁶ The ethanol-mediated decrease in wound vascularity causes increased wound hypoxia and oxidative stress.⁷⁷ Connective tissue restoration is also influenced by acute ethanol exposure, and results in decreased collagen production and alterations in the protease balance at the wound site. In summary, acute ethanol exposure can lead to impaired wound healing by impairing the early inflammatory response, inhibiting wound closure, angiogenesis, and collagen production, and altering the protease balance at

the wound site.

As mentioned previously, the host response to chronic alcohol exposure appears to be different from that of acute alcohol exposure. Analysis of clinical data indicates that chronic alcohol exposure causes impaired wound healing and enhanced host susceptibility to infections, but the detailed mechanisms that explain this effect need more investigation.

Cancer, Chemotherapy, and Radiation

Chemotherapeutic Drugs. Most chemotherapeutic drugs are designed to inhibit cellular metabolism, rapid cell division, and angiogenesis and thus inhibit many of the pathways that are critical to appropriate wound repair. These medications inhibit DNA, RNA, or protein synthesis, resulting in decreased fibroplasia and neovascularization of wounds.⁷⁸ Chemotherapeutic drugs delay cell migration into the wound, decrease early wound matrix formation, lower collagen production, impair proliferation of fibroblasts, and inhibit contraction of wounds.⁷⁹ In addition, these agents weaken the immune functions of the patients, and thereby impede the inflammatory phase of healing and increase the risk of wound infection. Chemotherapy induces neutropenia, anemia, and thrombocytopenia, thus leaving wounds vulnerable to infection, causing less oxygen delivery to the wound, and also making patients vulnerable to excessive bleeding at the wound site.

Impaired wound healing due to chemotherapeutic drugs such as Adriamycin is most common when the drugs are administered preoperatively or within 3 weeks postoperatively.⁸⁰ Additionally, low postoperative albumin levels, low postoperative hemoglobin, advanced stage of disease, and electrosurgery use have all been reported as risk factors for the development of wound complications.⁸¹

A newer generation of tumor chemotherapeutics include angiogenesis inhibitors, such as bevacizumab, which is an antibody fragment that neutralizes VEGF. These therapies work in conjunction with traditional chemotherapeutics to limit the blood supply to tumors, reducing their ability to grow. Wound healing complications, including an increase in wound dehiscence, have been described in patients on angiogenesis inhibitors.⁸² A caveat is that most patients on angiogenesis inhibitors are also on traditional chemotherapeutics, making it difficult to sort out whether angiogenesis inhibitors alone would perturb repair.⁸³ Nevertheless, current recommendations include discontinuation of angiogenesis inhibitors well in advance of any surgical procedures.

Radiation

Radiation is one of the most commonly used therapies for the treatment of multiple types of human cancer. It results in a wide range of acute and chronic toxicities, with poor health outcomes, and often become dose-limiting for patients and impairing their quality of life (QoL) and recovery in both the short and the long term.

4 Injury resulting from radiation and chemotherapy is initiated through two major paths: radiolytic hydrolysis and stimulation of the innate immune response. Of the two, oxidative stress is the best studied with respect to cancer treatment-associated tissue injury. After an initial exposure to radiation, there is immediate damage to the keratinocyte cells of the skin, which is accompanied by a simultaneous increase in free radicals, DNA damage, and inflammation. Radiation- or chemotherapy-induced oxidative stress leads to the production of oxygen free radicals; specifically the reactive oxygen species superoxides, hydrogen peroxides, and hydroxyl radicals that cause oxidative damage to the tissue. Inflammatory cells are recruited to the injured area, a process orchestrated by vasodilation and vascular permeability. On the cellular level, fibrosis involves the coordination of a variety of cell types largely mediated through the fibroblast. The infiltrating immune cells secrete cytokines that drive the differentiation of fibroblasts and other self-renewing cells into myofibroblasts which deposit collagens and other ECM proteins at and around the site of tissue damage.⁸⁴

Chapter 6

Hemostasis

Peter K. Henke and Thomas W. Wakefield

Key Points

- 1 At the same time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to localize thrombin activity to areas of vascular injury. Just as thrombin generation is key to coagulation, antithrombin is the central anticoagulant protein.
 - 2 The endothelial cell acts as a nonthrombogenic surface, and inflammation tips the balance to procoagulant state.
 - 3 Thrombosis and inflammation are closely linked, and may perpetuate each other. Leukocytes and chemokines are involved with normal DVT resolution. These essential inflammatory mechanisms may drive vein wall injury.
 - 4 Both acquired and inherited factors contribute to pathologic thrombosis; often occurring together.
 - 5 Heparin-induced thrombocytopenia (HIT) occurs in 0.6% to 30% of patients in whom heparin is given; severe thrombocytopenia associated with thrombosis (HITTS) is much less frequent. Cessation of heparin is critical.
 - 6 Factor VIII and IX deficiency states are involved in hemophilia A and B and von Willebrand disease.
-

BASIC CONSIDERATIONS

Coagulation is an essential homeostatic mechanism for survival, and involves tightly controlled processes to maintain vascular integrity including thrombosis localization, amplification, and neutralization. These coordinated steps occur at the vessel, cellular and subcellular levels. Thrombosis, directly or indirectly, is the underlying leading cause of death in the world, and is an essential part of surgery.

Platelets form the initial hemostatic plug after vascular injury, and are locally activated and aggregation induced (Fig. 6-1). Platelet aggregation is mediated by receptors that are part of the mammalian integrin family. This family includes the β_1 family, mediating platelet interaction with cells, collagen, fibronectin, and laminin; the β_2 family (LeuCAM), present on leukocytes mediating interactions between leukocytes and other cells important in inflammation; and the β_3 family (cytoadhesion), including the megakaryocyte-specific glycoprotein (Gp) IIb/IIIa receptor and the vitronectin (Vn) receptor present on platelets and other cells.¹ Platelet aggregation is mediated by GpIIb/IIIa, which binds fibrinogen, von Willebrand factor (vWF), fibronectin, Vn, and thrombospondin to activated platelets. These high-density receptors are hidden on inactivated platelets and become exposed on the surface of activated platelets.

Two platelet activation routes are thought to occur physiologically.² Without direct vessel damage, platelet activation may occur via tissue factor (TF) de-encryption and activation by protein disulfide isomerase (PDI), with factor VIIa generation and activation of platelets. Alternatively, subendothelial collagen may directly bind to GpVI and vWF, leading to platelet capture and activation. Of note, PDI inhibition can directly block experimental thrombus formation.³

Once stimulated, activated platelets contract, with externalization of negatively charged procoagulant phospholipids, including phosphatidylserine and phosphatidylinositol (termed platelet factor 3). This allows the coagulation proteins to assemble on the surface membrane of platelets, accelerating the coagulation reaction.⁴ During platelet activation, granules release their contents of calcium, serotonin, and membranes are exposed that are rich in receptors for factors Va and VIIa,^{5,6} as well as fibrinogen, vWF, and ADP, a potent activator of other platelets. vWF is responsible for platelet adhesion through binding to GpIb,⁷ whereas fibrinogen forms bridges between activated platelets by binding to GpIIb/IIIa on adjacent stimulated platelets.⁸ Platelets also release polyphosphates that activate factor XII and the

intrinsic pathway.⁹

While long thought to be a bystander in venous thrombosis (VT) as compared to the arterial system, the role of the platelet is now thought to play a critical role, as well as directing later inflammatory cell actions.^{10,11} First, recent clinical trials suggest antiplatelet therapy may reduce recurrent VTE.¹² Second, in stasis and nonstasis experimental murine VT, genetic deletion of vWF was associated with significantly reduced VT size and not restored with recombinant factor rVIII.¹³ Intravital microscopy also showed direct association of leukocytes and platelets in a growing acute thrombus. Consistently, platelets via GpIb₂, may promote VT by colocalizing leukocytes and coagulation factors at the site of injury or stasis in the vein.¹⁴

Once the platelet plug has formed, the stage is set for coagulation protein assembly (Fig. 6-2). Initiating agents for coagulation include subendothelial collagen and TF, usually from vascular injury.² There is also growing evidence that blood-borne TF associated with leukocytes, or circulating in soluble form, is also involved with venous thrombogenesis.^{15,16} Leukocyte adhesion to platelets may trigger leukocyte activation, causing recruitment of blood-borne TF onto the surface of leukocytes associated with thrombus, or recruitment of TF-positive leukocytes onto the growing thrombus.¹⁷ TF, both blood borne and local, activates the extrinsic pathway of coagulation by complexing with activated factor VII (VIIa), activating factors IX and X to factors IXa and Xa.^{16,18} Factor Xa, activated factor V (Va), ionized calcium, and factor II (prothrombin) form on the platelet phospholipid surface to initiate the prothrombinase complex, which catalyzes the formation of thrombin faster than can be achieved with factor Xa alone.

Thrombin is central to coagulation and acts to cleave fibrinopeptide A (FPA) from the α chain of fibrinogen and fibrinopeptide B (FPB) from the β chain. This leads to the release of fibrinopeptides and the formation of new fibrin monomers, which then cross-link, resulting in fibrin polymerization. Thrombin also activates factor XIII, which catalyzes the cross-linking of fibrin to make the clot firm, activates platelets, and activates factors V and VIII, two nonenzymatic cofactors, to Va and VIIIa. This is important because only activated factors Va and VIIIa are involved in coagulation. Factor XIIIa also cross-links other plasma proteins, such as fibronectin and α_2 -antitrypsin, resulting in their incorporation into clot.

Figure 6-1. Primary hemostasis is achieved initially with a platelet aggregation as illustrated. Note that platelet adhesion, shape change, granule release, followed by recruitment and the hemostatic plug at the area of subendothelial collagen (binds to GpVI) exposure are the initial events for thrombus formation. Platelets can also be activated by PDI with de-encryption of TF.

The intrinsic pathway of blood coagulation requires activation of factor XI to XIa. This may occur by both the contact activation system through activation of factor XII, plasma prekallikrein, and high-molecular-weight kininogen and, more important, through thrombin with negatively charged surfaces.¹⁹ Factor XIa activates factor XI autocatalytically and also catalyzes the conversion of factor IX to IXa. After activation, factor VIIIa dissociates from vWF and assembles with factors IXa and X. Factor IXa, factor X, ionized calcium, and thrombin-activated factor VIII (VIIIa) then assemble on the platelet surface in a complex called the *Xase complex* to catalyze the activation of factor X to Xa. Factor Xa then shunts into the prothrombinase complex for further amplification of thrombin formation.

The importance of a mechanism of factor XI activation independent of the contact activation system is apparent because patients deficient in those factors of the contact activation system, including factor XI, bleed, whereas patients deficient in factor XII, prekallikrein, and high-molecular-weight kininogen do not usually bleed.²⁰ The contact activation system is the most important coagulation process involved in extracorporeal bypass circuits, including cardiopulmonary bypass and extracorporeal membrane oxygenation.

Figure 6-2. The classical pathway showing the interface between the intrinsic pathway, extrinsic pathway, and the common pathway is illustrated with the ultimate production of thrombin. This catalyzes fibrin from fibrinogen, and then cross-linking the fibrin to form a stable clot.

NATURAL ANTICOAGULANT MECHANISMS

1 At the same time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to localize thrombin activity to areas of vascular injury. Just as thrombin generation is key to coagulation, antithrombin (AT) is the central anticoagulant protein (Fig. 6-3). This glycoprotein of 70-kD molecular weight binds to thrombin, preventing the removal of FPA and FPB from fibrinogen, prevents the activation of factors V and VIII, and inhibits the activation and aggregation of platelets. In addition, AT directly inhibits factors IXa, Xa, and XIa.

A second natural anticoagulant is activated protein C (APC), which inactivates factors Va^{21,22} and VIIIa, thus reducing the Xase and prothrombinase complex acceleration of the rate of thrombin formation. In the circulation, protein C is activated on endothelial cell surfaces by thrombin complexed with one of its receptors, thrombomodulin (TM).²³⁻²⁵ The formation of this thrombin-TM complex accelerates the activation of protein C compared with thrombin alone. Thrombin, at the same time, by binding to TM, loses its platelet-activating activity as well as its enzymatic activity for fibrinogen and factor V. Protein S is a cofactor for APC.

Another innate anticoagulant is tissue factor pathway inhibitor (TFPI). The protein binds to TF-VIIa complex, inhibiting the activation of factor X to Xa and the formation of the prothrombinase complex.²⁶ A fourth natural anticoagulant is heparin cofactor II.²⁷ Its concentration in plasma is estimated to be significantly less than that of AT, and its action is implicated primarily in the regulation of thrombin formation in extravascular tissues. Finally, thrombin is inactivated when it becomes incorporated into the clot.

FIBRINOLYSIS

In addition to natural anticoagulants such as protein C and S, physiologic clot formation is balanced by a contained process of clot lysis, which prevents thrombus formation from proceeding outside of the injured area (Fig. 6-4). The central fibrinolytic enzyme is plasmin, a serine protease generated by the

proteolytic cleavage of the proenzyme, plasminogen. Its main substrates include fibrin, fibrinogen, and other coagulation factors. Plasminogen, tissue plasminogen activator (tPA), and α_2 -antiplasmin (α_2 -AP) become incorporated into the fibrin clot as it forms. Plasminogen activators are serine proteases that activate plasminogen, by cleavage of a single arginine–valine peptide bond, to the enzyme plasmin. Plasminogen activation provides localized proteolytic activity.^{28–30} In fact, thrombin promotes tPA release from endothelial cells as well as the production of plasminogen activator inhibitor (PAI-1) from endothelial cells.^{31,32}

Figure 6-3. Antithrombin is a primary anticoagulant. Note antithrombin complexes with IIa to inhibit fibrin polymerization, as well as factor Xa, and an inactivating factor Va and VIIIa.

Figure 6-4. Hemostasis with thrombus production is a tight and intricate process that is locally confined. Balancing thrombus production is tissue plasmin activator and urokinase plasminogen activator which activates plasmin and causes thrombolysis. These are balanced by plasminogen activator inhibitor-1 and alpha-2-antiplasmin. Free plasmin is complexed rapidly. Fibrin degradation products, such as D-dimer are produced.

The major endogenous plasminogen activators include tPA and urokinase, and intrinsic factors, such as factor XII, prekallikrein, and high-molecular-weight kininogen. These later factors of the contact system are more important in clot lysis than thrombus formation. These enzymes may also liberate bradykinin from high-molecular-weight kininogen, resulting in an increase in vascular permeability,

prostacyclin (PGI₂) liberation, and tPA secretion. Finally, APC has been found to proteolytically inactivate the inhibitor to tPA, thus promoting tPA activity and fibrinolysis.³³

Fibrin, when digested by plasmin, yields one molecule of fragment E and two molecules of fragment D. In physiologic clot formation, fragment D is released in dimeric form (D-dimer),^{20,34} and is a marker for fibrinolysis of formed clot. An elevated D-dimer level after treatment of DVT is one biomarker that has been found to accurately predict an ongoing risk of recurrent VTE.³⁵

Two primary inhibitors of plasmin are important. First, α_2 -AP is released by endothelial cells and complexes with plasmin. In physiologic fibrinolysis, α_2 -AP is bound to fibrin and excess plasmin is readily inactivated. In plasma, PAI-1 is the primary inhibitor of plasminogen activators. It is secreted in an active form from liver and endothelial cells and stabilized by binding to Vn. PAI-1 levels are elevated by hyperlipidemia, and PAI-1 elevation appears to synergize with factor V Leiden genetic abnormalities.³⁶

In summary, coagulation is an ongoing process of thrombus formation, inhibition of thrombus formation, and thrombus dissolution. The central mediators are TF, platelets, thrombin, and plasmin. Abnormalities in coagulation occur when one process – thrombus formation, thrombus inhibition, or fibrinolysis – overcomes the others and dominates the delicate balance.

ENDOTHELIUM AND HEMOSTASIS

2 Through its ability to express procoagulants and anticoagulant factors, vasoconstrictors and vasodilators, as well as key cell adhesion molecules and cytokines, the endothelial cell is a key regulator of hemostasis (Fig. 6-5).³⁷ Vascular endothelium maintains a vasodilatory and local fibrinolytic state in which coagulation, platelet adhesion and activation, and leukocyte activation are suppressed.

Vasodilatory endothelial products include adenosine, nitric oxide (NO), and PGI₂. A nonthrombogenic endothelial surface is maintained by four main mechanisms including; endothelial production of TM and subsequent activation of protein C, endothelial expression of surface heparan- and dermatan sulfate, constitutive expression of TFPI by endothelium (which is markedly accelerated in response to heparin), and local production of tPA and urokinase plasminogen activator (uPA).^{37,38} Finally, the elaboration of NO and interleukin (IL)-10 by endothelium inhibits leukocyte adhesion and activation.

During states of endothelial disturbances such as injury, a prothrombotic and proinflammatory state of vasoconstriction is driven by the endothelial surface. Endothelial release of platelet-activating factor (PAF) and endothelin-1 promotes vasoconstriction.³⁸ Endothelial cells increase production of vWF, TF, PAI-1, and factor V to augment thrombosis with exposure to prothrombotic stimuli. Finally, in response to endothelial injury, endothelial cells are activated, resulting in increased surface expression of cell adhesion molecules, promoting leukocyte adhesion and activation.

THROMBOSIS, INFLAMMATION, AND RESOLUTION

3 After VT, an acute to chronic inflammatory response occurs in the vein wall and thrombus progressing from thrombus amplification, to organization, and vein recanalization (often at the expense of vein wall fibrosis and vein valvular damage). Initially, there is an increase in neutrophils (PMN) in the vein wall followed by monocytes/macrophages. Cytokines, chemokines, and inflammatory factors (e.g., tumor necrosis factor [TNF]) facilitate inflammation. The ultimate response of the vein wall depends on proinflammatory and anti-inflammatory mediator balance at the interface between the leukocyte, activated platelet, and endothelium.³⁹

Cell Adhesion Molecules

Selectins (P- and E-selectin) have been found to be intimately involved in this process (Fig. 6-6).⁴⁰ Selectins are the first upregulated glycoproteins on activated platelets (alpha granules) and endothelial cells (Weibel–Palade bodies). They mediate the adhesion of leukocytes, platelets, and even cancer cells in inflammation and thrombosis. The P-selectin receptor is P-selectin glycoprotein ligand-1 (PSGL-1). P-selectin:PSGL-1 interactions trigger the release of procoagulant microparticles (MPs), that support fibrin formation, thrombus growth, and increase monocyte TF expression.

MPs <1 micron fragments may be central for P-selectin's effect. It is believed that with initial thrombosis, P-selectin upregulation leads to MP formation. These procoagulant MPs, which may express

TF, are then recruited into the area of developing thrombosis, amplifying the process. Consistently, P-selectin gene deficiency, results in less MP formation, and less thrombosis.⁴¹ In an experimental study, the generation of procoagulant activity was shown to be dependent on P-selectin:PSGL-1 interactions related to MP formation.⁴² The procoagulant nature of these MP was demonstrated by their ability to normalize bleeding in factor VIII-deficient mice.

Figure 6-5. The endothelium is a primary interface allowing both anticoagulant functions in the resting state, with prostacyclin, NO, plasminogen activators, and thrombomodulin. Procoagulant proteins are expressed on activated endothelium including selectins, procoagulant proteins, such as the von Willebrand factor, TF, as well as PAI-1.

E-selectin, upregulated after P-selectin, is an important regulator of thrombus formation and fibrin content in a mouse VT model.^{43,44} Endotoxin-induced TF-mediated coagulation is enhanced in humans carrying the *S128R* E-selectin allele,⁴⁵ and patients homozygous for the *S128R* E-selectin allele have an increased risk for VTE recurrence, highlighting the importance of E-selectin in DVT.⁴⁶ E-selectin has been shown to be efficient at raising the affinity and avidity of 2 (CD18) integrins which support neutrophil trafficking to sites of acute inflammation and recruit platelets and red blood cells.⁴⁷

PSGL-1 has greatest affinity for P-selectin, and lesser affinity for E-selectin and L-selectin. The role of P-selectin in VT has been suggested by the study of a mouse with high fourfold higher circulating levels of P-selectin than wild type.⁴⁸ These mice are hypercoagulable based on clotting tests, and a receptor antagonist against the P-selectin receptor (rPSGL-Ig) reverses the hypercoagulability. Consistently, wild-type mice administered soluble P-selectin (sP-sel) become hypercoagulable. In models of VT, P-selectin inhibition given prophylactically decreases thrombosis in a dose-dependent fashion, and can treat established VT as effectively as heparin without anticoagulation.^{49,50}

Figure 6-6. The interaction between stasis injury and procoagulant syndromes are represented by Virchow triad. Endothelial and vascular injuries cause leukocytes and platelets to express P- and E-selectin and the PSGL-1 receptor. Microparticles are released which express TF. This stimulates the coagulation pathway, fibrin production, and thrombus amplification.

sP-sel is released from activated platelets and endothelial cells and levels rise significantly during pathologic conditions.^{51–53} sP-sel has been studied as a biomarker for DVT,^{51,54–56} combining Sp-sel with Wells score (clinical pretest probability of DVT) establishes the diagnosis of DVT. A sP-sel (≥ 90 ng/mL) combined with Wells score (≥ 2), showed a better PPV (91%) than D-dimer (≥ 500 ng/mL) combined with Wells score (≥ 2), which was 69%.⁵⁷

Other factors of importance to venous thrombogenesis include vWF, a factor that stabilizes procoagulant factor VIII to promote the initiation and formation of stable thrombus at the site of vascular inflammation and TF. Using a ferric chloride model of vein wall injury, it has been shown that occlusive thrombus formation is dependent on vWF.⁵⁸ Regarding TF, mouse models using gene-targeting and bone marrow transplantation technologies found that TF in the vessel wall is more important than TF from leukocytes for thrombus formation when there is no flow in the experimental model.⁵⁹ TF has been linked to circulating procoagulant MPs, particularly in cancer patients, cancer is associated with high levels of DVT, and TF activity is increased in cells treated with chemotherapeutic agents.⁶⁰ In addition, cancer patients with VTE were found to have elevated levels of microparticle TF compared to cancer patients without VTE.^{61,62}

Leukocytes and Thrombosis

Inflammatory cells are important to the process of thrombus recanalization and organization (Fig. 6-7).^{40,63} Thrombus resolution resembles wound healing, and involves both profibrotic growth factors, collagen deposition, matrix metalloproteinase (MMP) expression, and activation.^{64,65} As the thrombus resolves, a number of proinflammatory factors are released into the local environment, including interleukin-1 beta (IL-1 β) and tumor necrosis factor-alpha (TNF- α).⁶⁶ The cellular sources of these different mediators are probably leukocytes and smooth muscle-like cells within the resolving thrombus and adjacent vein wall. The fact that leukocytes invade the thrombus in a specific sequence suggests their importance in the normal thrombus resolution.⁶⁶

The first cell type in the thrombus is the PMN. Although PMNs may cause vein wall injury, they are essential for early thrombus resolution by promoting both fibrinolysis as well as collagenolysis.^{67,68} In a rat model of stasis VT, neutropenia was associated with larger thrombi at 2 and 7 days, and was correlated with increased thrombus fibrosis and significantly lower thrombus levels of both uPA and MMP-9.⁶⁹ Conversely, in a nonstasis VT model, PMNs may promote thrombosis.¹⁴ It is likely the timing of PMN influx and the amount of perithrombus blood flow that determines prothrombotic or prothrombolytic activities. Through processes that also involve the initial activation of leukocytes and platelets, PMNs form neutrophil endothelial traps (NETs), which are extracellular fragments of DNA containing histones and antimicrobial proteins.^{14,70} NETs provide a scaffold for thrombus formation and are prothrombotic.⁷¹

In order to investigate if plasma DNA is a surrogate for NETs in patients with DVT, and to determine correlations with other biomarkers of DVT studied in our laboratory, patients presenting to our diagnostic vascular laboratory were investigated.⁷² Patients were divided into positive for DVT by ultrasound, leg pain but negative for DVT by ultrasound, and control volunteers. Circulating DNA was significantly elevated in DVT patients, compared with controls. Of interest was a significant positive correlation of circulating DNA with C-reactive protein, D-dimer, vWF, and the Wells score (all $p < 0.01$).

The monocyte/macrophage is likely the most important cell for later DVT resolution.⁷³ Monocyte influx into the thrombus peaks at day 8 after thrombogenesis, and correlates with elevated MCP-1 levels, which has been associated with DVT resolution.⁷⁴ Targeted deletion of CC receptor-2 (CCR-2 KO) in the mouse model of stasis thrombosis was associated with late impairment of thrombus resolution, probably via impaired MMP-2 and MMP-9 activities.⁷⁵ Indeed, precedent exists in humans that the monocytic activation state may predict long-term DVT resolution.⁷⁶

Thrombi have been found to contain increasing amounts of both tPA and uPA activities as they resolve, and this activity is expressed by invading monocytes.^{77,78} In a recent study, mice genetically deleted for uPA had impaired thrombus resolution with reduced monocyte infiltration at the margins of the thrombus, with few neovascular channels present.⁷⁹ Mice gene deleted for tPA, however, were not similarly affected, suggesting that uPA, not tPA, is responsible for this activity.

Figure 6-7. The proposed resolution mechanism involves both early thrombolysis with a large distending clot and then, over time, a fibrotic thrombus that resembles scar tissue as produced. Note proinflammatory factors, as well as neutrophils (releasing NETs), platelets, and MMP are present early with subsequent vein wall injury related to collagenolysis and elastinolysis. Later, vascular smooth muscle cell proliferation appears to occur, with thrombus resolution with increased profibrotic growth factor such as IL-13 and TGF-β. This promotes collagen accumulation. Both PAI-1 and CCR7 are protective against fibrosis.

The local venous environment is by definition hypoxic, hypoxia-inducible factor-1 alpha (HIF-1α). A major angiogenic growth factor is HIF-1α. Experimental data in a stasis model of VT suggest that thrombosis stimulates increased vein wall HIF-1α, and that by exogenous stimulation of HIF-1α expression, thrombus recanalization was increased and associated with accelerated VT resolution.⁸⁰ Thus, thrombus resolution is in part dependent on neovascularization. The effect of mechanical stretch, such as by a VT, may also stimulate HIF-1α as well as MMP-2 and MMP-9, both leading to reduced vein contractility.⁸¹

Recent data linking inflammation to fibrosis demonstrate that inhibition of the inflammatory response can decrease vein wall fibrosis. In a rat model of stasis DVT, treated with either low-molecular-weight heparin (LMWH) or an oral inhibitor to P-selectin 2 days after establishment of thrombosis, inhibition of P-selectin significantly decreased vein wall injury (independent of thrombus size).⁸² The mechanism accounting for this protective effect is not yet known, but probably does not involve leukocyte blockade, because no differences in influx of monocytes into the vein wall were observed.

Loss of venous endothelium likely also contributes to the vein wall fibrosis, as well as the predisposition to recurrent thrombosis. An experimental model of DVT showed lower expression of homeostatic endothelial genes such as NO and TM than in controls, which correlated with loss of vWF positive cell luminal staining.⁸³ Other investigators have found that prolonged venous stasis is associated with decreased plasminogen activators, probably related to loss of endothelium.⁸⁴

Associated with the early biomechanical injury from DVT is an elevation of profibrotic mediators, including transforming growth factor-beta (TGF-β), interleukin-13 (IL-13), IL-6, and monocyte chemotactic protein-1 (MCP-1).^{82,85,86} These mediators are present within the vein wall and thrombus and may drive the fibrotic response. Although exogenous MCP-1 may hasten DVT resolution, it promotes organ fibrosis in vivo. The profibrotic growth factor TGF-β is also present in the thrombus and is activated with normal thrombolysis.⁸⁷ TGF-β may be a key mechanism promoting vein wall fibrosis.

Late fibrosis has been observed in our mouse model of DVT, which demonstrated a significant increase in vein wall collagen after stasis thrombogenesis.⁸⁸⁻⁹⁰ Based on experimental studies, elastinolysis and collagenolysis seem to occur early, as measured by an increase in vein wall stiffness, persisting through 14 days, and are accompanied by elevated MMP-2 and MMP-9 activities.^{85,89} Correlating with this increase in fibrosis is altered procollagen I and III gene expression, as well as an increase in MMP-2 and MMP-9 gene expression and activity. Genetic deletion of MMP-2 or MMP-2/9 is associated with decreased midterm vein wall fibrosis, possibly by modulating vein wall elastin/collagen metabolism as well as monocyte influx.^{64,65} It has been demonstrated that decreasing inflammation with a selectin inhibitor or with neutralizing IL-6 can also decrease vein wall fibrosis.^{43,91,92} Moreover, the thrombus size itself does not drive the vein wall injury response; rather the mechanism of thrombosis seems more important.^{85,93} Lastly, PAI-1 overexpression is associated with decreased vein wall fibrosis, in part by decreased MMP-2/9 activity.⁹⁰

ARTERIAL VERSUS VENOUS THROMBOSIS

Thrombosis in the arterial system occurs somewhat differently than in the venous system (Fig. 6-8). The elements required for the initiation of DVT were described by Virchow as stasis, endothelial injury, and hypercoagulability of the blood. In the arterial circulation, endothelial vascular injury (whether acute or chronic) is key to thrombosis. This is most clearly demonstrated by the typical atherosclerotic plaque. In advanced lesions, the lipid core of the plaque is rich in inflammatory cells, cholesterol crystals, and TF (generated by activated macrophages within the plaque).⁹⁴ Plaque ulceration exposes highly thrombogenic lipid to the bloodstream, activating coagulation, platelet aggregation, and leading to the deposition of clot.⁹⁵ Platelet deposition occurs at the apex of stenosis, the point of maximal shear force. The blood flow velocity itself regulates how quickly both thrombi form and dissolve.⁹⁶

A platelet-rich thrombus is observed in arterial thrombus while in contrast, venous blood stasis and changes in its composition (leading to hypercoagulability) incite the formation of thrombus from local procoagulant events, including small endothelial disruptions at venous confluences, saccules, and valve pockets.¹¹ Hypercoagulable states have classically been highly associated with VTE, but do play a role in cardiovascular disease as well.^{97,98} Moreover, HMG-CoA reductase inhibitors (statin) not only decrease atherothrombotic events, but also incident VTE,⁹⁹ suggesting some common pathogenic pathways.

PROCOAGULANT STATES

Acquired Procoagulant States

4 Most thrombotic clinical episodes have an identifiable cause, although environment risks and genetic predispositions to thrombosis may account for many of the VTE that manifest clinically.¹¹ Risk factors for arterial thrombosis are primarily related to atherosclerosis, and are detailed elsewhere.

The most common risk factors for VTE are prior DVT, malignancy, immobility, intravenous catheters, increased age, major surgery, trauma, infections such as pneumonia and urinary tract infection, and certain chemotherapies (Table 6-1).^{100–102} Certain medications such as oral contraceptives and hormonal replacement therapies also increase the risk of VTE.

Of primary importance to surgeons is how best to estimate perioperative VTE risk, and apply appropriate prophylaxis. This can be done with a screening form, such as that devised by Caprini et al.¹⁰³ and Pannucci et al.¹⁰⁴ Essentially, this is a focused assessment of VTE risks related to current illnesses and history that may not be fully covered in the routine history and physical. The recommendations are also well detailed in the routinely updated American College of Chest Physicians VTE evidence-based guidelines.¹⁰⁵ The higher the risk, the more intensive the prophylaxis, is the paradigm. For example, an outpatient hernia patient may require no prophylaxis outside of early ambulation where as a hip replacement in an obese patient would be best treated with anticoagulation as well as sequential compression devices for the lower extremities. However, all patients should be assessed for VTE risk.

Malignancy

Cancer represents an independent risk factor for the development of VTE, with a sixfold increased risk in cancer patients. Importantly, cancer patients undergoing surgical procedures have twice the risk of development of postoperative DVT.¹⁰⁶ Highest rates of VTE are seen in pancreas, stomach, and lung cancer. The malignancy itself activates a procoagulant phenotype by expression of TF by malignant cells, release of TF-bearing MPs, and increased activation of neutrophil extracellular traps – the downstream effects of which have been outlined above.¹⁰⁷

Despite considerable evidence supporting the use of prophylactic anticoagulation in cancer patients, many do not receive optimal pharmacoprophylaxis for DVT while inpatient.¹⁰⁸ An extended duration of therapy – 28 days – was found to be associated with a decreased incidence of DVT at the end of the study period; consequently, current guidelines recommend extended thromboprophylaxis in cancer patients after an operative intervention.¹⁰⁸

Figure 6-8. Depicted in **A** is the typical atherosclerotic thrombotic nidus, which includes rupture of a plaque, composed of smooth muscle, foam cells, and leukocytes. Platelets are the primary intermediary in arterial thrombosis, as well as TF. In figure **B**, increased coagulability, as well as vessel wall changes with procoagulant TF expression promotes thrombosis.

Inflammatory Bowel Disease

Since the first half of the last century, a link between inflammatory bowel disease (IBD) and VTE has been recognized. While there does appear some correlation between thrombosis and the inflammatory nature of the disease, the link between the inflammatory and coagulation cascades does not tell the whole story. There are several possible mechanisms for this increased tendency toward thromboembolic events under active investigation, including spontaneous platelet activation through the CD40–CD40L pathway.¹⁰⁹

A recent retrospective cohort study of the National Surgical Quality Improvement Program database demonstrated that the presence of IBD is an independent risk factor for postoperative VTE with an odds ratio of 2.¹¹⁰ Interestingly, there appears to be an increased tendency to form clot in unusual locations, such as cerebral and hepatic veins. Currently, guidelines recommend only standard pharmacologic thromboprophylaxis for patients with IBD.

Trauma

As with other acquired prothrombotic states, the systemic inflammatory milieu is associated with VTE in trauma patients. Activation of inflammatory pathways through TNF- α with increased circulating TF and procoagulant MP induces a prothrombotic state.¹¹¹ Incidence of VTE in trauma patients is around 2%, and this may be higher in patients with other risk factors, such as old age, obesity, and prolonged immobility after bone fractures.^{112,113} LMWH with application of pneumatic compression devices has been shown to be the preferred thromboprophylaxis in trauma patients, and this is reflected in anticoagulation guidelines.¹⁰⁵ However, optimal dosing regimens are not well defined.

Table 6-1 Acquired Hypercoagulable States

Risk	Relative Risk of VTE
Malignancy	++++
Trauma	++
Indwelling catheters	+
Surgery	++++
Pregnancy	+
HRT/OC	+
Lupus Anticoagulant	+++
Obesity	+
Postoperative infection	++++
IBD	+++
Prolonged immobility	++

HRT, hormone replacement therapy; IBD, inflammatory bowel disease; OC, oral contraceptive.
+, low risk; ++, moderate risk; +++, high risk; +++, very high risk.

Lupus Anticoagulant/Antiphospholipid Syndrome (Antiphospholipid Antibody)

Antiphospholipid antibody syndrome is a particularly virulent hypercoagulable state that results in both arterial thrombosis and VT and consists of an elevated antiphospholipid antibody titer in association with thrombosis, recurrent fetal loss, thrombocytopenia, and livedo reticularis. Strokes, myocardial infarction, visceral infarction, and extremity gangrene may also occur. Although the lupus anticoagulant has been noted often in patients with systemic lupus erythematosus (SLE), it does occur in patients without SLE. It may also be induced in patients by medications, cancer, and certain infections.¹¹⁴

A number of possible thrombotic mechanisms have been suggested, including inhibition of PGI₂ synthesis or release from endothelial cells,¹¹⁵ inhibition of APC by thrombin/TM,¹¹⁶ elevated PAI-1 levels,¹¹⁷ platelet activation,¹¹⁸ endothelial cell activation,¹¹⁹ and interference with the endothelial cell-associated annexin V anticoagulant activity.¹²⁰ Increased TF expression on monocytes and low free protein S plasma levels have also been found with the antiphospholipid syndrome and a history of thrombosis.^{121,122}

At least one-third of patients with lupus anticoagulants have a history of one or more thrombotic events, 70% or more being VTE.¹²³ Graft thrombosis has been observed in 27% to 50% of patients positive for antiphospholipid antibody.^{124,125}

For the diagnosis of antiphospholipid syndrome, both clinical and laboratory criteria are necessary.

For the clinical criteria, ≥ 1 must be present:

1. ≥ 1 clinical episode of, objectively confirmed, arterial, venous, or small vessel thrombosis.
2. Pregnancy morbidity: ≥ 1 unexplained fetal death @ ≥ 10 weeks EGA; ≥ 1 premature birth (≤ 34 th week of gestation) due to eclampsia, severe preeclampsia, or placental insufficiency; ≥ 3 unexplained consecutive spontaneous abortions @ < 10 weeks EGA.¹²⁶

For the laboratory criteria, ≥ 1 must be present:

1. LA (+) ≥ 2 occasions, at least 12 weeks apart, according to ISTH guidelines (prolonged PL-based clotting assay, lack of correction with 1:1 mix, and correction with excess PL).
2. ACLA and/or anti- $\beta 2$ glycoprotein-I antibody (medium or high immunoglobulin G (IgG) and/or IgM isotype titer ≥ 2 occasions, at least 12 weeks apart using standardized ELISA assays).

The prolongation in the aPTT is strictly a laboratory phenomenon. The dilute Russell viper venom time confirms the presence of a lupus anticoagulant.

There is imperfect agreement between diagnostic tests for this abnormality. Approximately 80% of patients with a prolonged aPTT will have a positive antiphospholipid antibody, but only 10% to 50% of patients with a positive antiphospholipid antibody will have a prolonged aPTT.¹²⁷

Heparin followed by warfarin has been recommended for the treatment of the antiphospholipid syndrome.^{114,123} For recurrent fetal loss, heparin or LMWH use through pregnancy is recommended. In patients with lupus anticoagulants, heparin is monitored by antifactor Xa levels.

Heparin-Induced Thrombocytopenia and Thrombosis Syndrome

5 Heparin-induced thrombocytopenia (HIT) occurs in 0.6% to 30% of patients in whom heparin is given, although severe thrombocytopenia associated with thrombosis (HITTS) is seen much less frequently.^{128,129} Approximately one half of HIT patients have thrombosis that is noted clinically or by duplex imaging. In an analysis of 11 prospective studies, the incidence was reported to be 3%, with

thrombosis in 0.9%.¹³⁰ Although earlier morbidity and mortality rates of 61% and 23% had been reported,¹¹⁶ with early diagnosis and appropriate treatment, these rates have declined to 6% and 0%, respectively.¹³¹ HIT is caused by a heparin-dependent IgG antibody that, when bound to platelet factor 4 (PF4), induces platelet aggregation in part by inducing MP formation.^{132,133} The antibody may not be heparin specific, as the degree of sulfonation of the heparin-like compound has been suggested to be critical for this aggregation.¹³⁴

Both porcine and bovine UFH as well as LMWH have been associated with HIT.¹³⁵ The syndrome usually begins 3 to 14 days after heparin is begun. Both arterial and venous thromboses have been reported, and even small exposures to heparin (heparin coating on catheters) can cause the syndrome.^{128,136} VTE associated with HIT is <1% for LMWH, while it is approximately 12% to 13% for UFH with a higher risk for mortality.¹³⁷

The diagnosis should be suspected when a patient experiences a 50% or greater decline in platelet count, when there is a fall in platelet count below 100,000/mL during heparin therapy, or in any patient who experiences thrombosis during heparin administration.¹³⁸ The syndrome may be difficult to diagnose as many hospitalized patients have multiple reasons for low platelet counts, and vigilance is important. A platelet count should be checked about every 2 days when on heparin therapy.

The laboratory diagnosis of HIT/HITTS is made by a number of assays. The serotonin release assay was the “gold standard” in the past. An ELISA test detecting the antiheparin antibody in the patient’s plasma directed against the heparin–PF4 complex is now commonly used.¹²⁸ This assay is less specific but more sensitive and is easier to perform and interpret than the serotonin assay. However, inappropriate testing is common when HIT is suspected. The 4Ts score is a validated measure of pretest probability with a high negative predictive value that, used appropriately, can limit expensive over-testing and unnecessarily subjecting patients to cessation of heparin and alternative anticoagulation.^{139,140}

When the diagnosis is made (clinically), cessation of heparin is mandatory. This includes removing heparin from intravenous catheters and flushes.¹³⁶ Warfarin should not be administered until an adequate alternative anticoagulant has been started to prevent thrombotic complications. A number of anticoagulants are now available to substitute for patients with this diagnosis. The direct thrombin inhibitor, argatroban, is FDA approved for this indication and shows no cross-reactivity to heparin antibodies.^{138,141} When using argatroban, it is important to keep in mind that the INR is artificially elevated with this agent. Fondaparinux has also been used for this indication.¹⁴²

Hypercoagulability Testing: Clinical signs of possible thrombophilia include thrombosis at a young age (<40), unprovoked thrombosis, recurrent thrombosis, thrombosis at unusual locations such as the mesentery, CNS venous sinus, and portal vein, a family history of thrombosis, particularly unprovoked, severe, and in those <50 years of age.¹⁴³ Testing for hereditary defects in patients with thrombosis with no family history has pros and cons. On the pro side, testing may: improve understanding of pathogenesis of thrombosis, identify and counsel affected family members, and obviate expensive diagnostic testing (e.g., CT scans) looking for a malignancy. On the con side, testing may identify patients with defects whose management would change, with the potential for overaggressive management, insurance implications for the patient arise, and the testing is rather costly.

In order to determine the efficacy of hypercoagulable testing, a multicenter international observational registry on clinical characteristics, treatment patterns, and outcome in consecutive patients with symptomatic, objectively confirmed acute VTE, was done. In this study, 22,847 patients were enrolled and 4,503 tested for thrombophilia. Of the total patient population, 8.4% had with factor V Leiden, 6.8% had PTG20210A, and 3% had activated protein C resistance (APC-R). The authors concluded that for the low incidence and in accordance with the recommendations made by other authors and international bodies, “the undertaking of thrombophilia testing on patients with a first episode of VTE is not advisable.”¹⁴⁴

A hypercoagulable screen should include routine coagulation tests such as the aPTT and platelet count, AT activity and antigen assay, protein C antigen and activity levels, protein S antigen level, and mixing studies to identify a lupus anticoagulant (if indicated); APC-R assay and factor V Leiden gene analysis; prothrombin G20210A genetic analysis; homocysteine level; an antiphospholipid antibody screen that includes anticardiolipin antibody; fibrinogen level; FVIII, FIX, and FXI levels and a functional plasminogen assay.

Inherited Procoagulant States

Defects with High Risk for Thrombosis

Antithrombin Deficiency. AT is a serine protease inhibitor (SERPIN) of thrombin, kallikrein, and factors Xa, IXa, VIIa, XIIa, and XIa (Table 6-2). It is synthesized in the liver and has a half-life of 2.8 days. AT deficiency, accounts for approximately 0.5% to 3% of episodes of VTE, the prevalence in the population is 0.2%, and it carries a 20× increased risk for VTE when heterozygous¹⁴⁵⁻¹⁴⁷ and may occur at unusual sites such as mesenteric or cerebral veins. Arterial and graft thromboses have also been described in AT deficiency.^{148,149} It is inherited in an autosomal dominant fashion most cases become apparent by 50 years of age.¹⁵⁰ Homozygous patients usually die in utero, whereas heterozygous patients usually demonstrate AT levels <70% of normal. Acquired AT deficiency results from liver disease, malignancy, sepsis, disseminated intravascular coagulation (DIC), malnutrition, and renal disease.¹⁴⁸ AT deficiency is divided into type I deficiency (quantitative) and type II deficiency (qualitative).

Table 6-2 Severity and Frequency of VTE due to Hypercoagulable States

	Frequency (%)	Site
High Risk for Thrombosis		
■ AT deficiency	0.5–3	Venous >> arterial
■ Protein C deficiency	3	Venous >> arterial
■ Protein S deficiency	3–6	Venous >> arterial
■ Antiphospholipid antibody syndrome	3–5	Venous > arterial
Lower Risk for Thrombosis		
■ Factor V Leiden	20–60	Venous >> arterial
■ Hyperhomocysteinemia	10	Arterial ~ venous
■ PT G20210A	4–6	Venous >> arterial
■ Dysfibrinogenemia	1–3	Venous > arterial
■ Dysplasminogenemia	<1	Arterial ~ venous
■ Elevated factors VIII, IX, and XI	1	Venous > arterial

AT, antithrombin; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; PAI-1, plasminogen activator inhibitor; VTE, venous thromboembolism.

The diagnosis of AT deficiency is suspected in a patient who cannot be adequately anticoagulated with heparin or who develops thrombosis while on heparin and is made by measuring AT antigen and activity levels. However, patients should not have been exposed to heparin or related compounds for at least 2 weeks as heparin decreases AT levels 30%.¹⁵¹ Conversely, warfarin increases AT levels.

For a patient with AT deficiency, anticoagulation with heparin requires the administration of fresh frozen plasma (FFP) to provide AT, 2 units every 8 hours, decreasing to 1 unit every 12 hours, followed by oral anticoagulation. A reasonable alternative includes anticoagulation with direct thrombin inhibitors such as argatroban or bivalirudin.¹⁰⁵ Aggressive prophylaxis against VTE is recommended during the perioperative period, and usually lifelong anticoagulation therapy is required after a first episode of significant VTE.

Protein C and S Deficiencies. Protein C and its cofactor protein S are both vitamin K–dependent factors synthesized in the liver with half-lives of 4 to 6 hours and 12 to 14 hours, respectively. The majority of cases of protein C or protein S deficiency are inherited as autosomal dominant. Patients present with VTE, often between the ages of 15 and 30 years.^{152,153} Heterozygous protein C deficiency is present in 1 in 200 to 500 individuals in the general population and in approximately 3% of individuals with VTE.¹⁴⁶ In a study of 10,000 healthy blood donors, protein C deficiency was noted in 1.45 per 1,000.¹⁵⁴ Protein deficiency is divided into a type I deficiency (quantitative) and a type II deficiency (qualitative).

Levels of protein C in those heterozygous deficient may overlap with lower limit normal levels. In addition to VTE, cases of arterial thrombosis have also been reported.¹⁵⁵ If present as a homozygous state at birth, infants usually die from unrestricted clotting and fibrinolysis, a condition of extreme DIC termed *purpura fulminans*. Patients heterozygous for protein C deficiency usually have antigenic protein C levels less than 60% of normal.^{156,157} Acquired protein C deficiency occurs with liver failure, DIC, and nephrotic syndrome.

Protein S is a cofactor to protein C in inactivating FVa and FVIIIa, and is regulated by complement C4b-binding protein. Inheritance of protein S deficiency is in an autosomal dominant pattern.^{157,158}

Approximately 40% of protein S circulates in a free active form, with the remainder bound to C4b-binding protein. Free protein S is functionally active as an anticoagulant. Protein S levels increase with age, and females have lower levels than males. The deficiency of protein S results in a clinical state identical to protein C deficiency with a VTE rate 5% to 7%, an estimated $8.5\times$ higher risk for the development of VTE.¹⁵⁹ The frequency of protein S deficiency ranges from 3% to 6% for those with VTE. Levels of protein S are reduced in liver disease, nephrotic syndrome, inflammation, OCP use, in pregnancy, and during breastfeeding. Nephrotic syndrome leads to a reduction in free protein S,¹⁶⁰ whereas inflammatory states such as SLE can result in an elevation of C4b-binding protein, reducing free protein S.

The diagnosis of protein C or S deficiency is made by measuring plasma protein C and S levels.^{34,161} For protein C, both antigen and activity are measured, whereas for protein S, only antigen is measured. A condition also exists in which there is an abnormality in the function of protein C itself, resulting in a decrease in protein C activity without a decline in antigenic protein C.¹⁵³

Treatment consists of anticoagulation, initially with heparin, usually followed by lifelong oral anticoagulation after a first thrombotic event. However, not all patients with low levels develop VTE. Many heterozygous family members of homozygous protein C-deficient infants also are unaffected.³³ Thus, the institution of anticoagulation therapy in patients should occur only following an episode of thrombosis. However, aggressive anticoagulant prophylaxis during perioperative periods or high-risk environmental situations is necessary for asymptomatic heterozygote carriers.

With the initiation of oral anticoagulation, blood may become transiently hypercoagulable as the vitamin K-dependent factors with short half-lives are inhibited (factor VII, protein C) before the other vitamin K-dependent factors (factors II, IX, and X).¹⁶² In someone already partially deficient in protein C or S, the levels of these anticoagulant factors will diminish even further with the initiation of warfarin. This results in temporary hypercoagulability, resulting in thrombosis in the microcirculation and warfarin-induced skin necrosis.¹⁶³ This leads to full-thickness skin loss, especially over fatty areas such as the breasts, buttocks, and abdomen. This complication can be prevented by initiating warfarin therapy under the protection of systemic heparin anticoagulation or a direct thrombin inhibitor.

Defects with Lower Risk for Thrombosis

Resistance to APC (Factor V Leiden). Resistance to APC has been reported to be present in 20% to 60% of cases of idiopathic VTE and is the most common underlying abnormality associated with VTE. This disorder is present in 1% to 2% of the general population.^{164–166} In a study of 4,047 Americans, the carrier frequency of this mutation was 5.3% for Whites, 2.2% for Hispanic Americans, 1.25% for Native Americans, 1.2% for African Americans, and 0.45% for Asian Americans, with no gender differences.¹⁶⁴ It confers a relatively low risk for thrombosis, however, and is more common in whites than in nonwhite Americans.¹⁶⁴

As a result of the substitution of a single amino acid, glutamine for arginine, at position 506 in the protein for factor V, caused by a nucleotide substitution of guanine for adenine at 1,691 in factor V gene, hypercoagulability is conferred by resistance to inactivation of factor Va by APC.^{167–169} Additionally, less VIIIa is interfered with, compounding the hypercoagulability. Factor V Leiden accounts for 90% of APC-R.

Thrombotic manifestations are noted in those individuals both homozygous and heterozygous for this mutation. The relative risk for VTE in patients heterozygous for factor V Leiden is 7-fold, whereas the relative risk is 80-fold for those homozygous for factor V Leiden.^{165,168} In contrast to factor deficiency states, persons homozygous for this mutation usually do not die in infancy. Additionally, thrombosis is potentiated in the presence of additional acquired risk factors.^{168,170}

Combined defects with other hypercoagulable states, such as protein C and S deficiency or prothrombin G20210A, are not uncommon and increase the thrombotic risk.^{171,172} In addition to cases of VTE, recurrent VTE is also more common in patients with this entity, with a relative risk 1.4-fold.^{166,173} Although VTE predominates in patients with this syndrome, arterial thrombosis has also been reported.¹⁷⁴

The diagnosis of APC-R is made by a clot-based functional assay with the addition of APC (modified aPTT). Additionally, genetic analysis should be performed to confirm heterozygosity versus homozygosity, as treatment decisions may be different between the two states.

Treatment options for APC-R after VTE include anticoagulation, initially heparin or LMWH, followed by oral anticoagulation. The long-term use of warfarin is controversial. No data exist to suggest that long-term warfarin should be given after a first episode of VTE in a patient heterozygous for the

mutation. The fact that APC-R is a relatively low risk for recurrent thrombosis (1.4-fold) suggests that not all patients after their first episode of VTE need long-term anticoagulant treatment. Patients must be evaluated in light of their overall risk for bleeding versus thrombosis.¹⁵²

Prothrombin G20210A Polymorphism. Prothrombin (factor II), a vitamin K-dependent factor synthesized in the liver, becomes thrombin when activated. A genetic polymorphism in the distal 3' untranslated region of the gene for prothrombin, a transition from guanine to adenine at the 20210 nucleotide of the prothrombin gene, has been described in patients with VTE.¹⁷⁵ This results in a normal prothrombin but at increased levels.^{153,170,176} This polymorphism, confers an increased risk for VTE by 2.8-fold, and is associated with 4% to 6% of patients with VTE.^{152,177–180} Of patients with spontaneous DVT, the incidence is 7% to 16%.^{181,182} This is the second most common cause for hypercoagulability in Caucasians and its prevalence is 1% to 2% of Caucasians. The thrombosis risk is increased in pregnant women,¹⁸³ in women with early myocardial infarctions,¹⁷⁹ and in synergy with factor V Leiden.¹⁷⁰ Most patients are heterozygous for this mutation, and whites are more often affected than those of Asian or African descent.¹⁷⁹ Genetic analysis is the marker for this abnormality.¹⁸⁴

Patients who present with VTE should be treated according to current standards and akin to the treatment for heterozygous factor V Leiden. Individuals with prothrombin G20210A who have recurrent episodes of VTE should undergo lifelong anticoagulation, as should those patients with both prothrombin G20210A and factor V Leiden.¹⁷⁰

Hyperhomocysteinemia. Hyperhomocysteinemia has been a known risk factor for atherosclerosis and vascular disease for more than 25 years, though a direct cause and effect relationship has not been established.^{185–187} However, a recent meta-analysis suggests the risk of VTE to be 2.5-fold with elevated homocysteine levels.^{187–192}

Two enzyme deficiencies, N⁵, N¹⁰, methylenetetrahydrofolate reductase (MTHFR) or cystathionine beta synthase, are responsible for elevated homocysteine levels.¹⁹³ Although mutations in these enzymes are not infrequent, the common polymorphism in MTHFR alone is not a factor in either the elevation of plasma homocysteine or thrombosis.¹⁹⁴ Acquired causes include advanced age, smoking, coffee consumption, low dietary folate, and low vitamin B₆ and B₁₂ intake. Higher levels are also associated with diabetes mellitus, cancer, hypothyroidism, lupus IBD, and medications such as metformin, methotrexate, anticonvulsants, theophylline, and levodopa.^{195,196}

Hyperhomocysteinemia has a frequency of 10% in patients with a first episode of VTE, and is a risk factor for VTE in those younger than 40 years,¹⁸⁹ in women,¹⁸⁵ and for recurrent VTE in patients between 20 and 70 years of age.¹⁸⁶ The combination of hyperhomocysteinemia and factor V Leiden results in an increased risk of venous and arterial thromboses.¹⁹⁷ Elevated plasma homocysteine results in abnormal endothelial function.^{198–202} Fasting homocysteine levels are determined from serum, usually on two occasions. The test may also be performed after a methionine oral loading regimen.^{203,204}

Homocysteine elevation is treated with folate supplements. Although the association between hyperhomocysteinemia and VTE has been established, treatment to lower homocysteine levels and the long-term effects of such treatment on procoagulant activity have yet to be validated.¹⁸⁵

Other Disorders Associated with Thrombosis

Defective Fibrinolysis/Dysfibrinogenemia/Lipoprotein(a). Abnormal plasminogens (dysplasminogenemias), although rare (<1%), have been described in cases of spontaneous arterial or VTE.²⁰⁵ Both type I quantitative and type II qualitative deficiency states have been described. Other defects in fibrinolysis may affect up to 10% of the normal population.²⁰⁶ Abnormal fibrinogens may account for 1% to 3% of patients with VT and those presenting with digital ischemia.²⁰⁷ Numerous molecular defects have been classified. Defective thrombin binding or resistance to plasmin-mediated breakdown has been described.²⁰⁸ Although not clearly documented, defects in plasminogen activators, tPA, or uPA may incite thrombotic events.²⁰⁹ Moreover, elevated PAI-1 has been associated with DVT and myocardial infarction.²⁰⁵ Although the relationship between VTE and abnormal fibrinolysis is debated, it is clear that in the postoperative period there is a connection between fibrinolysis and VTE.^{205,210,211} Additionally, PAI-1 is upregulated by thrombin, endotoxin, and IL-1, explaining the elevated circulating levels of PAI-1 during infections.²¹²

Lipoprotein(a), associated with LDL, has both atherogenic and prothrombotic properties.^{213–215} It prevents plasminogen from binding to cells or fibrin and inhibits fibrinolysis.²¹⁶ Elevated levels of lipoprotein(a) have been associated with VTE in childhood; it is a weak thrombotic risk factor in

adults.^{217–219} When an individual with thrombosis presents with one of the previously mentioned abnormalities, standard anticoagulation is necessary.^{220,221}

Abnormal Platelet Aggregation. It has been recognized for some time that there are patients who have thrombosis and may have hyperactive/hyperresponsive platelets but this entity is poorly defined. Diabetes mellitus, which is known to be associated with hyperactive platelets and hyperlipidemic states, may be a contributing factor. Hyperactive platelets have been noted during graft thrombosis in peripheral vascular reconstructions.¹¹⁷ Although platelet aggregation assays may be helpful in making the diagnosis, these assays are not commonly performed or standardized and, thus, the incidence and importance of platelets to thrombosis are not well known. Bleeding time measurements are not specific, and not recommended for making this diagnosis. This condition has been called “sticky platelet syndrome” and both arterial and venous events have been reported.¹⁵¹

Standard anticoagulant treatment is recommended for this condition. Aspirin and the thienopyridine derivatives such as clopidogrel may be useful, but their utility is unknown.²²²

Elevated Procoagulant Factors: VIII, IX, and XI

Elevated prothrombotic factors have only recently been associated with primary and recurrent VTE.^{152,223} A dose–response effect has been observed; and elevated factor VIII has been best studied.^{223–225} Factor VIII:C above the 90th percentile is associated with a 5-fold increased risk of VTE.^{225,226} Factor VIII:C elevation is also affected by blood type and race. The risk is $6.7\times$ after adjusting for age, sex, factor V Leiden, prothrombin G20210A, and duration of Coumadin therapy.²²⁷ In African American women, a statistically higher level of factor VIII has been found than in the white and Asian populations.²²⁸ Elevation of factor XI above the 90th percentile is associated with a 2-fold increase in VTE, independent of other hypercoagulability factors.²²⁹ Similar increases in VTE risk have been observed with elevated factor IX.²³⁰ Acquired and environmental factors precipitate VTE in patients with elevation of these factors, as opposed to inherited deficiencies of AT, protein C, and protein S that confer higher VTE risk.²³¹

The diagnosis is made by the direct measurement of these factors with activity assays. However, since the carrier protein for factor VIII is vWF which is an acute-phase reactant, measurement of factor VIII levels should be combined with an acute-phase reactant such as CRP or ESR. If VTE occurs with one of these factor elevated, standard anticoagulant management should be undertaken.²²¹

Disseminated Intravascular Coagulation

DIC is a primary form of acute thrombosis. Causes of DIC include sepsis, trauma, pancreatitis, obstetric complications such as abruptio placentae or amniotic embolism, transplant rejection, malignant tumors, certain snake bites, hematologic malignancies, and hepatic failure. Coagulation in DIC is activated by the release of TF into the circulation causing unregulated activation of the coagulation cascade, leading to massive thrombin production and fibrin generation. Fibrinolysis then becomes activated as well, leading to bleeding in the later, hemorrhagic stages of the syndrome because of the consumption of clotting factors, depletion of fibrinogen, and unchecked plasmin activity. The diagnosis of DIC is a clinical one, which requires consideration of the gestalt of the patient. Laboratory values in DIC reveal a downtrend in platelet count – even within the normal range, decreased fibrinogen level, prolonged PT, and concomitant elevation in fibrin split products and the presence of a positive D-dimer test. The treatment of DIC requires treatment of the underlying condition. The need for platelet or plasma transfusion is based on the presence of hemorrhage, rather than on particular laboratory values.²³²

BLEEDING DISORDERS

Although the surgeon deals more often with procoagulant states than bleeding disorders, it is important to recognize these disorders when they occur.

Coagulation Factor Deficiency

Coagulation factor deficiency states are important causes of bleeding and the most common are factor VIII and IX deficiency states, termed hemophilia A and B, and type I von Willebrand disease (vWD).

6 Hemophilia A is inherited as a sex-linked recessive deficiency of factor VIII, with fewer cases secondary to spontaneous mutation. The incidence of this abnormality is approximately 1 in 5,000 births.²³³ Clinical findings range from bleeding into joints and muscles, epistaxis, hematuria, and

bleeding after minor trauma, to prolonged postoperative bleeding, retroperitoneal bleeding, and intramural bowel hemorrhage. Laboratory screening tests usually reveal a prolongation of the aPTT along with decreased factor VIII levels; other test results are normal. The minimum level of factor VIII required for hemostasis is 30%, and spontaneous bleeding is uncommon with factor VIII levels greater than 5% to 10% of normal. Levels less than 2% constitute severe, 2% to 5% moderate, and greater than 5% mild deficiency.²³⁴ Although the half-life of factor VIII is 2.9 days in normal subjects, the half-life of factor VIII concentrates is only 9 to 18 hours.²³³ Levels between 80% and 100% of normal should be attained for surgical bleeding or life-threatening hemorrhage. Acquired deficiency has been reported to occur with the development of antibodies to factor VIII after therapy. Inhibitor antibodies develop in approximately 10% to 15% of patients with hemophilia A, although the incidence of antibody formation may be much higher in previously untreated patients and in those with severe hemophilia A.

Recombinant factor VIII preparation has been developed and tested in children and infants. Despite the development of low levels of inhibitors in 20% of children at a mean 9 days after first administration, these inhibitors either disappeared or remained at low levels.²³⁵

Factor IX deficiency (Christmas factor), known as hemophilia B, is transmitted as an X-linked recessive trait. It may also be acquired because of enhanced factor IX clearance in states such as the nephrotic syndrome, abnormal protein production in vitamin-K deficiency, and acquired specific inhibitors to factor IX in various autoimmune diseases, such as SLE. It is clinically indistinguishable from hemophilia A, and laboratory screening tests reveal a prolonged aPTT, with other test results normal, although a greater proportion of patients have only mild or moderate deficiency.²³⁶ Severe deficiency (approximately 30% of cases) is defined as a level of activity less than 4% of normal, whereas moderate deficiency is reported with activity levels between 20% and 40%.²³⁴ Treatment consists of plasma or factor IX concentrates and vitamin-K. It has been recommended that levels greater than 30% be achieved for hemostasis.

vWF causes platelet adhesion to collagen, initiating platelet plug formation. It also forms a complex with factor VIII in the blood. Produced in endothelial cells and megakaryocytes (compared with the liver for factor VIII), it has a circulating half-life of 6 to 20 hours. vWD, a deficiency of vWF, is the most common of the inherited coagulation disorder. A number of different subtypes have been identified for its deficiency state, and the syndrome is transmitted as both autosomal dominant (heterozygous) and autosomal recessive (homozygous) forms. Variants include types I and III (quantitative decreases in normal-appearing vWF) and type II (qualitative abnormalities in structure and function of vWF).²³⁷ vWF deficiency is probably as common as hemophilia A, although the true incidence may surpass what is generally appreciated because many mild cases probably remain undiagnosed.

The classic syndrome is caused by a reduction of factor VIII activity (although not as great as in hemophilia A) and vWF (vWF–factor VIII complex). Clinical manifestations include easy bruisability, mild to moderate epistaxis, gingival bleeding, menorrhagia, rare joint or muscle bleeding, prolonged bleeding following surgery, and subcutaneous bleeding. Spontaneous bleeding is not as common as in hemophilia A.

Abnormal laboratory tests include a prolonged bleeding time; a decreased level of factor VIII activity; decreased immunoreactive levels of the vWF; and abnormal platelet aggregation response to ristocetin. The most reliable source of vWF is cryoprecipitate, although many concentrates of factor VIII have vWF present and show promise. Desmopressin acetate (DDAVP) is available for the treatment of mild cases of type I vWD and type 2a and 2b, serum levels of 25% to 50% are needed for hemostasis. In other type II states and type III vWD, factor VIII concentrates are necessary. Recombinant factor VIII/vWF concentrates that avoid the infectious risks of transfusion are available.

Rare Factor Deficiencies

Other specific factor deficiencies are much less common and receive only a brief mention here. These include factors II, XI, V, VII, and X. These can be measured by serum assays, although this is not routinely available in many hospitals. The treatments are primarily FFP concentrates to give back the clotting factors.

Deficiencies of fibrinogen can also lead to bleeding disorders. This is the only factor deficiency state in which the TCT is prolonged. It is generally believed that a fibrinogen level of 100 mg/mL should be achieved to stop bleeding related to fibrinogen abnormalities. Fibrinogen deficiency may also occur from consumption during DIC and from primary fibrinolytic states.

Platelet Disorders

Platelet disorders are another important cause of bleeding. Inherited defects of platelet receptors include defects of GpIIb/IIIa (Glanzmann's thrombasthenia), characterized by impaired platelet binding to vWF, fibrinogen, and fibronectin. In patients with defects in GpIb (Bernard–Soulier syndrome), the absolute number of platelets is decreased, the platelets are larger, and platelet aggregation and adhesion are abnormal. Acquired deficits occur in uremia, both GpIb and GpIIb/IIIa receptors are defective, resulting in impaired adhesion and aggregation. Acquired deficits also occur in patients who previously received platelet transfusions and then acquire immune-mediated antiplatelet antibodies.

Abnormalities in Fibrinolysis

Abnormalities in fibrinolysis may play a role in abnormal bleeding disorders. Genetic or acquired deficiencies in α_2 -AP may be associated with bleeding, whereas deficiencies in factor XIII (fibrin stabilizing factor) may lead to highly lysable clot. α_2 -AP deficiency is treated with ϵ -aminocaproic acid or tranexamic acid. Homozygous patients with factor XIII deficiency and less than 1% of normal plasma activity often show bleeding from the umbilical cord at birth, bleeding after trauma or surgery, and delayed bleeding 24 to 36 hours later. Screening test results include a shortened euglobulin lysis time. A specific assay for factor XIII activity exists. Treatment consists of FFP, cryoprecipitate, and factor XIII concentrates.

Chapter 7

Inflammation

Matthew R. Rosengart and Timothy R. Billiar

Key Points

- 1 Innate immunity, a system already poised to respond prior to any stimulus, provides the initial defense against microbes. Subsequent reinforcement is provided by the more specific adaptive immune system, which possesses exquisite specificity for subsequent exposure to individual microbes and the capacity to learn and modify subsequent responses to repeated exposures. Both are composed of cellular and humoral components.
 - 2 Implicit with the capacity for pathogen elimination is the potential for destruction of host tissues. Numerous regulatory mechanisms provide temporal and spatial control of the inflammatory processes, including programmed cell death (i.e., apoptosis).
 - 3 Over 30 randomized controlled clinical trials have been conducted to assess the efficacy of modulating inflammation, in particular systemic cytokine concentrations, in reducing mortality.
 - 4 The T_H1 inflammatory response (i.e., cell-mediated immunity or delayed-type hypersensitivity) is induced by interleukin-12 (IL-12) derived from phagocytes and provides one major arm of the adaptive immune response; it is mediated by $CD4^+$ and $CD8^+$ lymphocytes and macrophages, which regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses.
 - 5 The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils. As the cellular effectors of humoral immunity, they provide the other major arm of the adaptive immune response, which is mediated by T_H2 $CD4^+$ cells, B cells, plasma cells, and antibodies.
 - 6 The complement system is integral to both innate and adaptive immunity and has the capacity to independently eliminate organisms and facilitate host defense by marking foreign particles for phagocytosis through opsonization.
 - 7 Additional systems, including the vascular (i.e., vasodilatation, adhesion receptors, kinin cascade) and neuroendocrine (i.e., adrenocorticotrophic hormone [ACTH], arginine vasopressin [AVP], corticotropin-releasing hormone [CRH]), integrate with the immune system, sharing similar mediators and their receptors, to orchestrate an intense, coordinated response to any injurious/septic insult.
 - 8 Danger-associated molecular patterns (DAMP) are the endogenous equivalent of PAMPS, represent danger signals or “alarmins,” and share many characteristics similar to cytokines. They may be released following nonprogrammed cell death, such as necrosis, or secreted as mediators by immune cells, under which circumstance they may facilitate the inflammatory response.
 - 9 Our immune system differentiates pathogens and damaged cells from self using evolutionarily ancient sets of recognition molecules called pattern recognition receptors (PRR), which bind conserved molecular structures found in large groups of pathogens, termed pathogen-associated molecular patterns (PAMPs), an example being the toll-like receptors (TLR).
-

Our appreciation for the complexity and our understanding of the integrated mechanisms collectively called “inflammation” has undergone considerable revision since the initial description of the four cardinal signs and symptoms by Celsus in first century AD: “rubor et tumor cum calore et dolore,” redness and swelling with heat and pain.¹ Centuries lapsed before John Hunter postulated that inflammation provides a survival mechanism to preserve the host. Ironically, he commented that an exuberant inflammatory response could be deleterious. These are all too true, as the pathologic sequelae of excessive inflammation (i.e., acute respiratory distress syndrome [ARDS], multiple organ dysfunction syndrome [MODS]) are encountered ever more frequently as technology affords survival of the initial

insult.¹ The 19th century witnessed milestone contributions to our understanding of this process as Rudolph Virchow detailed the cellular pathology of inflammation, Julius Cohnheim provided microscopic details of the acute phases of inflammation (vasodilatation, edema formation, and leukocyte emigration), and Elie Metchnikoff described the events of phagocytosis.¹⁻³ The integration of these new data created a novel new paradigm of cellular and humoral concepts of inflammation, both of which were deemed critical in host defense against foreign pathogens.

In the 20th century, technological advancements in molecular biology and biochemistry facilitated more detailed investigation and enabled the rapid expansion of knowledge of the many interwoven facets of the inflammation process. Evidence began to accumulate that the ramifications of these processes extended beyond the confines of the insult. Many humoral mediators, in addition to local effects, influenced distant targets as well, such as the liver and neurohormonal centers. Recently it has become clear that the immune system, endocrine system, and nervous system comprise an integrated network sharing similar mediators and their receptors. Such an integrative view, introduced by J. Edwin Blalock, when combined with Hans Selye's concept of stress, led to the contemporary understanding of sickness behavior, defined by Robert Dantzer as a highly organized strategy of the organism to fight infections and to respond to other environmental stressors. Hence, what originated nearly two millennia ago as a simple concept founded upon a constellation of signs and symptoms is now considered an intense, coordinated interplay of the nervous, vascular, endocrine, and immune systems to any injurious insult. It is the culmination of millions of years of evolution. Without it, life would be an arduous, painful, and brief existence, at best.

This chapter attempts to summarize this enormous quantity of information. An initial description of the elements involved in inflammation will provide the foundation upon which to discuss the sequence of events and interactions that comprise the inflammatory cascade.

INNATE VERSUS ADAPTIVE IMMUNITY

1 Innate immunity, a system composed of both cellular and humoral components, already poised to respond prior to any stimulus, provides our initial security against invading microbes.⁴ Phylogenetically it is ancient and conserved, notably providing the primary mechanism of invertebrate host defense. The response it provides is uniform and consistent with each successive infection. Subsequent reinforcement is provided by the more specific and targeted efforts of the adaptive immune system. In contrast to innate immunity, and as the name would suggest, it “adapts” and subsequent exposure to the inciting elicits responses of increased magnitude and defensive capabilities during.⁴ This exquisite specificity for individual microbes, the capacity to “learn,” “remember,” and modify subsequent responses to repeated exposures, has provided the impetus for the name.

Both arms of immunity are composed of cellular and serum components. In the adaptive immune response this has been divided into humoral immunity, which is mediated primarily by antibodies, and cell-mediated immunity. These are not distinct systems and form an integrated system of host defense.

CELLULAR COMPONENTS

Neutrophils

Neutrophils are integral to both innate and humoral immunity, providing the initial defense against invading viral, bacterial, and parasitic pathogens. This importance is underscored by the fact that 55% to 60% of the hematopoietic output of bone marrow is dedicated to the production of neutrophils.⁵ On exiting the marrow they circulate for 7 to 10 hours before taking up residence in the tissues for 1 to 2 days (Table 7-1).^{6,7} They are uniquely sensitive to minute concentration gradients of microbial products and inflammatory mediators and rapidly accumulate at sites of infection, where they ingest and dispose of a wide array of pathogens with their vast microbicidal armamentarium. This pathogenicity, however, carries with it an implicit capacity for host injury and accordingly, neutrophil function must be tightly regulated.

Recruitment

Neutrophil recruitment, conceptually, is a sequence of events progressing from (1) initial adhesion to activated endothelium, to (2) subsequent extravasation and emigration toward inflammatory foci, to (3)

the ultimate elimination of foreign microorganisms through phagocytosis, the generation of reactive oxygen species (ROS), and the release of microbial substances.⁴

After injury, local and regional vasodilation induces hyperemia which facilitates the leukocyte delivery to the focus of injury. Extravasation of plasma creates edema, and in combination with the release of vasoactive substances leads to hemoconcentration, which promotes the peripheral margination of leukocytes.^{8,9} Circulating neutrophils transiently interact with the endothelial cell surface molecules during “rolling,” a process that involves a series of loose and reversible attachments between the neutrophil and endothelium. (Fig. 7-1). These interactions, prerequisite for subsequent tighter cell–cell interactions, are mediated by the family of selectin receptors which bind with their counterligands, the sialyl Lewis family and other fucosylated and sulfated structures. E-selectin and P-selectin are present on endothelium and L-selectin is found on leukocytes.⁴

After stimulation by inflammatory mediators (thrombin, histamine, complement fragments, oxygen species, lipopolysaccharide [LPS], and cytokines such as IL-1, TNF α , and IFN γ), the vascular endothelium expresses P- and E-selectin, which engage neutrophil surface glycoprotein P-selectin glycoprotein ligand 1 (PSGL-1) or sialyl Lewis. P-selectin is stored intracellularly and can be rapidly mobilized for expression within minutes of cellular activation. Endothelial cells also translocate ligands for neutrophil L-selectin and release mediators like platelet-activating factor (PAF) and IL-8. Cytokines such as TNF α , granulocyte-macrophage colony stimulating factor (GM-CSF), and granulocyte colony stimulating factor (G-CSF) increase the affinity of leukocyte L-selectin for its counterreceptor. In addition to mechanical anchorage, these selectins induce signal transduction pathways that influence cellular function. P-selectin facilitates neutrophil degranulation and superoxide production, and cross-linking L-selectin primes the neutrophil for increased superoxide production.^{10–12}

After rolling, L-selectin is rapidly shed in preparation for leukocyte diapedesis and emigration into the interstitium. Subsequent exposure to chemoattractant gradients results in conversion of the neutrophil to a state of tight stationary adhesion (Fig. 7-1). The receptors mediating this interaction are members of the β_2 integrin family, most importantly leukocyte function antigen-1 (LFA-1, CD11a/CD18) and Mac-1 (CD11b/CD18). Their expression is enhanced in response to selectin binding, and thus explains the prerequisite nature of the early cell–cell interactions to neutrophil recruitment. Both integrin receptors engage the intercellular adhesion molecules ICAM-1 and ICAM-2 in mediating adhesion; yet, each provides additional important functions. Leukocyte emigration is primarily an LFA-1–dependent process, as mice deficient in this receptor exhibit reduced neutrophil attachment to ICAM-1 and endothelial cells. By contrast, mice lacking Mac-1 demonstrate impaired degranulation, superoxide production, and phagocytosis. Mac-1 also binds fibrinogen, heparin, and factor X and is implicated in neutrophil phagocytosis-induced apoptosis, a process essential for resolution of the inflammatory process (see below). The very late antigen 4 (VLA-4) binds vascular cellular adhesion molecule 1 (VCAM-1) and may provide an additional mechanism for tight adhesion. In addition to providing mechanical anchorage, these receptors interact with the cytoskeleton and other structural proteins and signaling cascades and are thought to represent a *biochemical* link between the external environment and intracellular signal transduction cascades that induce a cellular phenotype more appropriate for the inflammatory environment (Fig. 7-2).^{13–15}

Table 7-1 Leukocyte Subsets

Cell	Neutrophil	Monocyte	Lymphocyte	Eosinophil	Basophil
Size (μm)	13	16–20	9–16	12–16	15
Differential (%)	40–75	2–6	20–45	1–6	<1
Life span	6 h to 7 d	1 d to years	Months to years	8 to 12 d	1 year
Activators	G-CSF, IL-8	M-CSF, GM-CSF, IFN- γ , TNF α	IL-2, IL-12 (T _H 1), IL-4 (T _H 2)	G-CSF, IL-5	G-CSF, IL-3

G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; T_H, helper T cell; TNF, tumor necrosis factor. Modified from Burkitt G, Young B, Heath JW, eds. *Wheater's Functional Histology: A Text and Colour Atlas*. 3rd ed. Edinburgh, New York: Churchill Livingstone; 1993.

Figure 7-1. Leukocyte recruitment. 1. Circulating leukocytes express integrins in a low-affinity conformation. 2. Exposure to activated endothelium leads to rolling, which is mediated by L-selectin and P-selectin on the neutrophil and E-selectin on endothelium. 3. Leukocyte exposure to cytokines released by macrophages phagocytosing pathogens induces a high-affinity integrin conformation. Tight leukocyte–endothelial adhesion involves integrin engagement with counterligand expressed on the endothelium. 4. Subsequent exposure to chemokines leads to diapedesis, which is further mediated by the family of β_1 and β_2 integrins. (Adapted from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

Once tightly adhered, neutrophils must diapedese between endothelial cells and across the basement membrane to arrive at the focus of inflammation. Platelet/endothelial cell adhesion molecule 1 (PECAM-1) and integrin-associated protein are integral to transmigration (Fig. 7-1).^{13,14,16,17} PECAM-1 is concentrated along the intercellular junctions of endothelial cells, and both leukocyte and endothelial PECAM-1 appear to be essential for neutrophil and monocyte diapedesis. Other candidate receptors include the β_1 integrins, or very late antigens (VLA), which possess affinity for many constituents of the extracellular matrix, including laminin, fibronectin, and collagens, the β_3 family of integrins including the glycoprotein (gp) II β III α and the vitronectin receptor.⁴ Further “directions” for migration to the focus of inflammation are delivered by the concentration gradients of chemotactic factors, including complement C5a, IL-8, LTB₄, and the bacterial product N-formylmethionyl-leucyl-phenylalanine (fMLP).^{18–20}

The clinical significance of even minor derangements in any aspect of this process is evident in the disease leukocyte adhesion deficiency, characterized by complete absence of CD18, and therefore all β_2 integrins. Patients usually succumb to recurrent skin and mucosal infections within the initial 10 years of life.⁴

Phagocytosis

Microbial elimination commences upon first encounter with a foreign pathogen. It is facilitated by opsonization, a process in which microbes are coated by immune globulins and/or complement, which subsequently bind to their respective cell surface receptors, Fc γ Rs and Mac-1.^{21–23} Neutrophils constitutively express low-affinity immune globulin receptors Fc γ RII and Fc γ RIII and can be induced to express high-affinity Fc γ RI by incubation with IFN γ or cross-linking β_2 integrins.^{5,24} Complement-dependent phagocytosis is mediated by interactions between the leukocyte Mac-1 receptor and the complement opsonin iC3b.

Once engaged, Fc γ Rs are phosphorylated on tyrosine residues within an immunoreceptor tyrosine activation motif (ITAM) by the Src family kinases.²⁴ These phosphorylated sites serve as docking regions for a variety of proteins, in particular Syk. The importance of Syk is underscored by the observation that mice deficient in Syk are incapable of ingesting IgG-opsonized particles. A series of enzymes are subsequently activated including phosphoinositol 3-kinase, phospholipase C (PLC), and protein kinase C. Ultimately, the actin cytoskeleton undergoes rearrangement and the local plasmalemma is remodeled in the formation and sealing of the phagosome.^{4,24}

This immature phagosome undergoes a series of maturation steps, whereby it acquires the machinery necessary for the killing and disposal of internalized microorganisms. Alterations in cytosolic calcium concentration induce the fusion of secretory vesicles and granules containing the microbicidal armamentarium with the immature phagosome.²⁴ Proteins effected by calcium concentration and that

may govern phagosomal maturation include synaptotagmins, actin, calmodulin, and the Src family of kinases.²⁴ The soluble N-ethylmaleimide-sensitive-fusion-protein attachment protein receptor (SNARE) proteins are thought to assist in fusion by engaging cognate receptors on the target membrane and approximating the two membranes. Antibodies to the SNARE 5, syntaxin 6, and SNAP-23, inhibited exocytosis of azurophilic and specific granules, respectively.²⁴

Figure 7-2. Integrin Signaling. Integrins comprise a large family of cell surface receptors that are composed of 2 subunits, α and β , and are activated by dimerization. The cytoplasmic tails are devoid of enzymatic activity, and hence, signal transduction is effected by adapter proteins that connect the receptor to the cytoskeleton, cytoplasmic kinases, and transmembrane growth factor receptors. As integrins bind the extracellular matrix they become clustered and associated with the cytoskeletal proteins talin, paxillin, and vinculin and signaling complexes. Actin stress fibers form, which increase integrin clustering. Ultimately, focal adhesion kinase (FAK) is recruited via interactions with talin and paxillin or with the β integrin subunit. Subsequent autophosphorylation on tyrosine 397 provides a binding site for the Src homology 2 (SH2) domain of Src. The Src kinase phosphorylates a number of focal adhesion components including paxillin and tensin and p130CAS, a docking protein that recruits Crk, which can subsequently activate proximal elements in the JNK cascade of the MAPK family. FAK may also be phosphorylated by Src on tyrosine 925, creating a binding site for the complex of the adapter Grb2 and Ras guanosine 5'-triphosphate exchange factor mSOS. These interactions also lead to activation of MAPK cascades, and ultimately the induction of a variety of genes. (Adapted from Giancotti F & Ruoslahti E. *Integrin Signaling*. *Science* 1999;1028-1032)

Neutrophil Granules and Secretory Vesicles

Neutrophils exhibit an oxygen-dependent “respiratory burst” pathway that generates toxic oxygen derivatives and an oxygen-independent pathway that utilizes toxic proteinases.²⁵ These two microbicidal arms are compartmentalized into four distinct granules or vesicles (Table 7-2).²⁶ They are mobilized in a hierarchical fashion in response to gradual elevations in the intracellular calcium level, which parallels the current needs of the cell.²⁷ They also contain adhesion molecules and important inflammatory mediators that help further orchestrate the involvement of other cells.

Primary, or azurophil (affinity for the dye azure A), granules target the destruction of phagocytosed organisms (Table 7-2). The myeloperoxidase (MPO) within these granules generates hypochlorous acid (HOCl) from products generated by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and also imparts the characteristic greenish color of pus.^{9,27} Other major constituents include (1) α -defensins, cytotoxic proteins that scaffold into transmembrane pores within the microbial cell wall and perturb the maintenance of vital transmembrane gradients, and (2) bactericidal/permeability-increasing (BPI) protein, which binds to gram-negative organisms and induces rearrangement of membrane lipids and inhibits growth.²⁷⁻³⁰ Elastase cleaves constituents of the extracellular matrix, including

proteoglycans, collagen (types I, III, IV), and fibronectin and, of course, elastin.³¹ Azurocidin is chemotactic for monocytes and stimulates LPS-induced release of IL-6 and TNF α from monocytes.^{4,27}

Table 7-2 Neutrophil Granules and Secretory Vesicles

Azurophil Granules	Specific Granules	Gelatinase Granules	Secretory Vesicles
Membrane			
Myeloperoxidase (MPO)	Lysozyme	Gelatinase	Plasma proteins
Lysozyme	Phospholipase A ₂	Lysozyme	
Cathepsins	Gelatinase	β_2 -Microglobulin	
Elastase	Collagenase	Acetyltransferase	
Proteinase 3	Lactoferrin		
Azurocidin	TNF		
BPI	β_2 -Microglobulin		
Defensins	Histaminase		
iNOS	Heparinase		
α 1-Antitrypsin	uPA		
α -Mannosidase			
Sialidase			
Acid mucopolysaccharide			
β -Glycerophosphatase			
Elastase			
Cytosol			
CD63	Mac-1	Mac-1	Mac-1
CD68	SNAP proteins	SNAP proteins	SNAP proteins
	CD15	Cytochrome b558	Cytochrome b558
	CD66	fMLP R	CR1
	CD67	DAG-deacylating	CD14
	Cytochrome b558	enzyme	CD45
	Fibronectin R	uPA R	fMLP R
	Laminin R		uPA R
	Vitronectin R		C1q R
	Thrombospondin R		
	fMLP R		
	uPA R		

BPI, bactericidal/permeability-increasing protein; CD, cluster of differentiation; CR1, complement component C3b; DAG, diacylglycerol; fMLP, N-formylmethionyl-leucyl-phenylalanine; iNOS, inducible nitric oxide synthase; R, receptor; TNF, tumor necrosis factor; uPA, urokinase-type plasminogen activator. Modified from Faurschou M, Borregaard N. Neutrophil granules and secretory vesicles in inflammation. *Microbes Infect* 2003;5(14):1317–1327.

Specific granules are rich in antimicrobial substances that are released extracellularly (Table 7-2).²⁶ Lactoferrin, by sequestering iron, retards bacterial growth and can bind bacterial cell membranes and induce irreversible membrane damage and lysis.²⁷ Phospholipase A₂ (PLA₂) participates in the degradation of bacterial membrane phospholipids. Lysozyme, present in all granules, is a cationic antimicrobial peptide that cleaves peptidoglycan polymers of bacterial cell walls. Gelatinase and collagenase are other extracellular matrix degrading enzymes.²⁷ These granules also possess receptors for a variety of extracellular matrix proteins and cell surface ligands (i.e., β_2 integrin Mac-1) that mediates firm adhesion to the endothelium. In addition to the mechanical function of cellular anchorage, engagement of these receptors with their respective counterligands induces phenotypic alterations such as degranulation and enhanced ROS production.^{4,27}

Gelatinase granules contain matrix metalloproteases, zymogens that upon proteolytic activation degrade the interstitial matrix including collagens, fibronectin, proteoglycans, and laminin; this may facilitate neutrophil extravasation and migration (Table 7-2). They too are a source of cell surface adhesion molecules.^{4,27,30}

Secretory vesicles contain many of the cell surface adhesion molecules essential for leukocyte recruitment. Their membranes are dense with the β_2 integrins LFA and Mac-1, the complement receptor CR1, the LPS receptor CD14, and the Fc γ RIII. Through fusion with the plasmalemma, the cell surface is enriched with these receptors, which facilitates firm neutrophil-endothelial engagement and the capacity to respond to a variety of stimuli.^{4,27} Not surprisingly, because of the essential nature of leukocyte recruitment, secretory vesicles possess the lowest threshold for release and thus released earliest, followed by gelatinase, specific, and azurophil granules (Table 7-2).²⁷

Table 7-3 Major ROS and Their Metabolism

Ros Molecule	Main Sources	Enzymatic Defense Systems	Products
Superoxide (O ₂ • ⁻)	Leakage from electron transport chain Activated phagocytes Xanthine oxidase Flavoenzymes	Superoxide dismutase Superoxide reductase	H ₂ O ₂ + O ₂ H ₂ O ₂
Hydrogen peroxide (H ₂ O ₂)	From O ₂ • ⁻ via superoxide dismutase NADPH oxidase Glucose oxidase Xanthine oxidase	Glutathione peroxidase Catalase Peroxiredoxins	H ₂ O + GSSG H ₂ O + O ₂ H ₂ O
Hydroxyl radical (O ₂ • ⁻)	From O ₂ • ⁻ and H ₂ O ₂ via transition metals		
Nitric oxide (NO)	Nitric oxide synthases	Glutathione/TrxR	GSNO

NADPH, nicotinamide adenine dinucleotide phosphate; ROS, reactive oxygen species; TrxR, thioredoxin.

Oxidative Burst and Oxidant Metabolites

The generation of toxic oxygen metabolites and ROS is the cardinal characteristic of the neutrophil, though is also a defensive quality of the monocyte/macrophage. Their essential antimicrobial properties are equally destructive to host tissues and implicated in the pathophysiology of many inflammatory disorders (Table 7-3). Thus, a delicate balance must be maintained between ensuring elimination of the offending pathogen and minimizing host damage.

A free radical is any species possessing one or more unpaired electrons. They are categorized under the broader term ROS, which encompasses all molecules capable of radical formation. Despite a very brief existence (10⁻¹¹ to 10⁻⁶ seconds) extensive damage may occur through the induction of free radical chain reactions. Species underlying both physiologic and pathophysiologic inflammation include the following: the superoxide anion (O₂•⁻), the hydroxyl radical (•OH), hydrogen peroxide (H₂O₂), the singlet oxygen, and the reactive nitrogen intermediates nitric oxide (NO) and peroxynitrite (ONOO⁻) (Table 7-3). Counterintuitive to their role in cell destruction, recent evidence also supports a role of ROS in intracellular signal transduction.³² Thus, in addition to their antimicrobial properties, ROS can modulate the immune response by activating inflammatory cells and inducing proinflammatory cytokine secretion.^{33,34}

2 Implicit with the capacity for pathogen elimination is the potential for destruction of host tissues. Hence, numerous regulatory mechanisms provide temporal and spatial control of the ROS production. The NADPH oxidase complex itself exists in a disassembled state, and only upon cell activation and the need for ROS production are the subunits approximated and enzymatic function enabled.³⁵ In addition, high plasma and tissue concentrations of proteinase inhibitors provide continuous surveillance and systemic control. However, such regulation is incomplete as evidenced by diseases such as rheumatoid arthritis, chronic obstructive pulmonary disease, and autoimmune vasculitis, which are the consequence of damage due to neutrophil-derived products.³⁵

NADPH oxidase is a heteromeric complex composed of six subunits: flavocytochrome b558, the electron transporting apparatus comprises gp91(phox) and p22(phox); the cytosolic complex p40(phox), p47(phox) and p67(phox); and the oxidase factor rac-2 (Fig. 7-3).³⁵ Microorganisms or high concentrations of chemoattractants bind to cell surface receptors and initiate oxidase activation, heralded by phosphorylation of p47(phox). Cytochrome b558 (gp91 and p22), which exists within the plasmalemma and the membranes of specific granules and secretory vesicles, is recruited by phagocytosis and granule fusion. Phosphorylation of p47(phox) induces a conformation change that enables its incorporation within the membrane, wherein it facilitates the translocation of rac2 and p67(phox), and stabilizes the association of this cytosolic complex with cytochrome b558, thereby rendering the complex functional.³⁵

At the redox center of the oxidase an electron is transferred from NADPH to oxygen, thereby generating superoxide.³⁶

Other mechanisms of superoxide production include uncoupling of xanthine dehydrogenase system, uncoupling of mitochondrial and endoplasmic reticulum (ER) electron transport chains, and nonenzymatic reactions such as autooxidation of hemoglobin.^{37,38}

Figure 7-3. NADPH oxidase assembly. In the resting neutrophil, the cytochrome subunits gp91 and p22 are tightly bound in the membrane. P47(phox), p67(phox) and rac-s complex are in the cytosol. On activation, GDI releases rac-2, and p47(phox) becomes phosphorylated. This causes translocation of rac-2, p47(phox), and p67(phox) to the membrane and complex formation with the cytochrome components, thereby completing the assembly of the active oxidase. (Redrawn from Burg ND, Pillinger MH. The neutrophil: function and regulation in innate and humoral immunity. *Clin Immunol* 2001;99(1):7–17.)

Superoxide is relatively weak and of low bactericidal potency. However, its membrane permeability and role as a reactant in reactions yielding highly toxic products confers upon it a high potential for cellular and tissue damage.³⁶

Superoxide can spontaneously or enzymatically (superoxide dismutase) dismutate into hydrogen peroxide.^{35,36}

It can also be converted to the more potent hydroxyl radical through the metal-catalyzed Haber–Weiss reaction.^{35,36}

or through the Fenton equation^{35,36}

Under physiologic conditions, lactoferrin found in neutrophil specific granules provides the iron catalyst for the Haber–Weiss reaction. In the Fenton reaction, superoxide or other biologic reducing agents such as lactate or ascorbate donate electrons to generate the ferrous ions required to react with hydrogen peroxide to produce the hydroxyl radical.^{35,36,39}

The hydroxyl anion is highly reactive and induces DNA strand breaks and base hydroxylations leading to adenosine triphosphate (ATP) depletion and gene mutations. It can attack lipid side chains of membrane phospholipids to form hydrogen peroxide and lipid hydroperoxides in a process called lipid peroxidation. These products can disrupt membrane function, serve as substrates for the production of cytotoxic aldehydes, or uncouple calcium-ATPase and increase cytosolic calcium concentration. Recent data also support a mechanism by which oxidation of critical sulfhydryl residues on the ryanodine receptors induces an “open” configuration and a leak of intracellular ER calcium into the cytosol.⁴⁰ This elevation of cytosolic calcium activates calcium-dependent proteases and phospholipases that propagate cellular damage.³⁹

Superoxide can react with nitric oxide to produce peroxynitrite (ONOO⁻) and hydroxyl radical.^{36,41}

The hemoprotein MPO yields the potently bactericidal HOCl from the reactants chloride and H₂O₂. HOCl oxidizes amino acids, nucleotides, and hemoproteins, can activate neutrophil collagenases and permit unabated elastase injury by inhibiting α1-antitrypsin, and contribute to hydroxyl radical and singlet oxygen production.^{33,39,42} Though short-lived, subsequent reactions with secondary amines generate secondary chloramines, which are equally toxic but much more stable. These metabolites can oxidize similar cellular components. They can combine with halide anions to generate toxic free halides or with taurine chloramines that induces membrane attack complex (MAC) complement formation.^{33,39,42}

In light of the pivotal role of MPO during inflammation and pathogen elimination, it is surprising that MPO deficiency is common and relatively benign. Though MPO-deficient neutrophils show early depressed bacterial killing, bactericidal function normalizes within 60 minutes.⁴³ It is hypothesized that though bacterial killing is impaired, post-phagocytosis-oxidase-dependent neutrophil apoptosis is normal, resulting in appropriate regulation of the inflammatory response.⁴³

Singlet oxygen, a highly reactive and extremely short-lived species, is formed by an input of energy to O₂ that reverses the spin direction of one of the outermost unpaired electrons away from a parallel spin. It is produced during reactions of the MPO–H₂O₂–halide system and is a potential product of superoxide dismutation and the Haber–Weiss reaction. It is highly electrophilic, reacting with compounds containing electron-rich double bonds and may react with membrane lipids to produce peroxides.³⁹

The destructive potential of these ROS for both host and pathogen necessitates a mechanism of continuous tight spatial and temporal regulation. The oxidase complex itself exists spatially disaggregated; only upon cellular activation are its constituents assembled and enzymatic function restored (Fig. 7-3).^{35,43} As elegant is the mechanism by which to control ROS production, so too are the measures employed to eliminate these products when no longer needed. Superoxide, the proximal reactant necessary for many of the ROS generating reactions, is removed by both spontaneous and enzymatic (superoxide dismutase) dismutation to H₂O₂ (Fig. 7-4). H₂O₂ is subsequently reduced to oxygen and water by catalase.^{36,39} In the extracellular environment, this function is performed by GSH peroxidase, a selenium-dependent enzyme that reduces H₂O while oxidizing reduced GSH to its oxidized form. The utilization of N-acetylcysteine, a reducing agent that restores GSH, reduces hepatocellular injury in an animal model of warm liver ischemia/reperfusion.³² It has also been shown to reduce contrast-induced nephropathy in patients undergoing imaging procedures requiring the use of iodinated contrast.⁴⁴ Mechanisms for preventing hydroxyl radical-induced tissue damage include the binding of transition metal ions by albumin, ceruloplasmin, haptoglobin, lactoferrin, and transferrin.^{33,36,39} Taurine is a scavenger for HOCl. Other antioxidants that may assist in controlling the reaction include vitamins E (tocopherol) and C. Vitamin C has many antioxidant properties, including the ability to regenerate α-tocopherol. It can prevent activation of neutrophil-derived collagenase and is a powerful scavenger of HOCl, superoxide, singlet oxygen, and hydroxyl radicals. Carotenoids have long double bonds to attract and sequester free radicals. Uric acid is a powerful scavenger of water-soluble radicals such as HOCl and singlet oxygen. It can also bind copper and iron ions to suppress hydroxyl radical formation. Stress proteins or heat-shock proteins (HSPs) are induced by oxygen radicals and ischemia and may play a role in defense. Furthermore, heme oxygenase-1 (HO-1) catalyzes the cleavage of heme to biliverdin, which is subsequently converted to bilirubin, an efficient free radical scavenger.^{33,36,39}

All of the aforementioned participants of the NADPH oxidase are vital for health, as evidenced by those who suffer from chronic granulomatous disease (CGD).^{35,43} These patients have deficient superoxide production and experience ineffective inflammatory reactions to infection. They commonly suffer from repeated bacterial infections (pneumonia, cutaneous abscesses and hepatic and perihepatic abscess, and osteomyelitis) by organisms that are catalase positive (*Staphylococcus aureus*). Organisms that produce large amounts of peroxide are less of a threat as the neutrophils can utilize bacterial peroxide to produce toxic metabolites. The use of prophylactic antibiotics and IFNγ has reduced the frequency of serious infections in this patient population.^{35,43}

Figure 7-4. Scavengers of ROS. (Redrawn from Klebanoff SJ. In: Gallin JI, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:723.)

Neutrophil Extracellular Traps and NETosis

The arsenal of antimicrobial products and mediators possessed by neutrophils to fulfill the tasks of killing and eliminating pathogens is vast and impressive. However, another distinct antimicrobial “weapon” was recently described, in which neutrophils extrude a lattice of chromatin and histones to entrap and then kill invading pathogens. The characteristic feature is the presence of neutrophil nuclear DNA in the extracellular space. These structures were entitled neutrophil extracellular traps (NETs), and the process of NET formation called NETosis. Attached to this DNA backbone is an array of microbicidal agents that are typically compartmentalized inside the azurophilic, specific and gelatinase granules: neutrophil elastase (NE), cathepsin G, and MPO. Distinct from apoptosis, the process does lead to cell death, though clearly contributes to pathogen control. It is conserved in various vertebrates, insects, and even plants, and several microorganisms exhibit mechanisms of resistance to NETs, both of which may highlight the importance of this process. Recent data suggest that excessive NETosis or ineffective NET clearance may underly diseases or syndrome characterized by excessive inflammation, including autoimmunity.^{45–47}

Pathogens (i.e., bacteria, fungi, viruses, and protozoa) and their subcellular components, such as LPS, M1 protein, and fMLP induce NET formation. Similarly, sterile insults, inflammatory stimuli (e.g., PAF, IL-8, TNF α , NO), and chemical compounds (PMA, ionomycin) all can stimulate NETosis. The process begins with engagement of the aforementioned stimuli with TLRs, Fc receptors, cytokine, and complement receptors located on the neutrophil cell surface. Subsequent calcium release stimulates PKC activity and assembly of functional NADPH oxidase, leading to ROS and NO production. ROS is/are requisite for NET formation, as antioxidant scavengers (e.g., N-acetylcysteine) attenuate the process. Interestingly, individuals with CGD, a disease characterized by insufficient ROS production, inefficiently produce NETs. The chromatin undergoes decondensation followed by mixing of nuclear and cytoplasmic components with granulate antimicrobial contents. Plasma membrane rupture ensues with the release of chromatin decorated with granular proteins into the extracellular space.^{45–47}

NETs are able to trap almost all pathogens, including those too large to be phagocytosed. Indeed, it is proposed that trapping by NETs is one of the most important functions that limits microbial spread. The antimicrobial functions of NETs are mediated by the microbicidal compounds accompanying the chromatin: NE, MPO, histones, cathepsin G, proteinase 3, lactoferrin, calprotectin, and antimicrobial peptides such as defensive or the cationic LL37. However, the histones H1, H2A, H2B, H3 and H4 themselves also possess powerful antimicrobial effects.

As fundamental as NETosis is for microbial defense, excessive formation or ineffective clearance of NETs is proposed to lead to several pathologic conditions. During acute lung injury a high concentration of stimulating factors promotes NETosis and the release of NE, LL-37, and ROS, which may exacerbate injury. In cystic fibrosis, the high concentrations of DNA due to NETosis are thought to underlie the high mucus viscosity.^{45–47} Several autoimmune diseases are also characterized by perturbed NETosis, and more than 70% of NET components are potent autoantigens. Small vessel vasculitis is characterized by antineutrophil cytoplasmic antibodies reactive against PR3 and MPO. Externalization of IL-17 in the

extracellular traps of neutrophils and mast cells is now thought to be central to the pathogenesis of psoriasis. In systemic lupus erythematosus (SLE), an imbalance between NET formation and clearance may underlie the systemic tissue damage that occurs. In fact, decreased NET degradation correlates with renal disease. NETs may also activate complement, thereby amplifying the disease. Furthermore, the neutrophils from patients with various autoimmune diseases appear more prone to NETosis.^{45–47}

NETs may also serve as a link between inflammation and thrombosis. They can provide a stimulus and scaffold for thrombus formation by promoting platelet and RBC adhesion and by concentrating effector proteins and coagulation factors. Activated endothelium produces compounds that, upon contact with neutrophils, stimulate NETosis, which in turn, promotes endothelial damage.^{45–47}

Regulation of Neutrophil Activity

In addition to the previously described mechanisms for controlling the inflammatory response of neutrophils, there is substantial evidence supporting the role of apoptosis in halting and resolving the neutrophil-derived inflammation (Box A).⁴⁸ Within 90 minutes of phagocytosis, over 250 genes are induced, of which more than 30 encode proteins integral to at least three distinct apoptotic pathways.⁴⁸ These observations suggest that the mechanism inducing apoptosis is initiated quite proximal in the inflammatory cascade, in fact, just subsequent to phagocytosis. The timely execution of a controlled cell death program in human PMNs is essential for preventing damage to healthy tissues and for the resolution of infection. Furthermore, evidence suggests that the phenotype of other immune cells, including monocytes and macrophages, is altered after encountering and phagocytosing apoptotic neutrophils. Thus, apoptotic neutrophil particles may function to downregulate the inflammatory function of neighboring cells. In some circumstances of infection or trauma, neutrophil apoptosis may be delayed, which might contribute to prolonged or a failure to resolve inflammation.

The inflammatory capacity of neutrophils is also transcriptionally regulated. Genes encoding proinflammatory mediators or signal transduction molecules such as receptors for IL-8, IL-10, IL-13 are downregulated early after activation and decrease rapidly after the initiation of apoptosis.⁴⁸ In addition, regulating oxidative stress and ROS achieve high priority as the genes involved in glutathione and thioredoxin metabolism and heme catabolism are upregulated as is the production of reduced glutathione.⁴⁸ Hence, activation-induced apoptosis in neutrophils stimulates self-directed regulation, an event that likely facilitates removal of neutrophils by macrophages. As aforementioned, removal of apoptotic neutrophils by activated macrophages also appears to serve a role in modifying their function and halting the inflammatory response.

Mononuclear Phagocytes

Monocytes circulate for about 1 to 2 days, whereafter, they constitutively hone to a particular tissue (i.e., lung, peritoneum) to differentiate into macrophages possessing a phenotype specific to the resident tissue (dendritic cells [DCs] of the skin, kupffer cells of the liver) (Table 7-1).^{4,49,50} Resident macrophages are typically found at interfaces with blood (liver and spleen) and with lymph, where they can readily detect, ingest, and destroy invading organisms.³⁹ Mononuclear cells function as antigen-presenting cells (APC) in T cell-mediated adaptive immune responses, presenting antigen in the appropriate context to effector T cells. They provide service integral to both innate and adaptive immune responses. Evidence also supports their role in providing an “alarm” both locally and systemically through the release of intracellular proteins (i.e., high-mobility group box 1 [HMGB1]) expressing DAMP that can function as a danger signal (see below).

Recruitment

Monocytes are recruited and emigrate to foci of inflammation utilizing similar mechanisms of adhesion and diapedesis as described for neutrophils (Fig. 7-1). PAF, C5a, the CC chemokines, regulated on activation, normal T cell-expressed and secreted (RANTES), MIP-1 α , and chemokines of the membrane cofactor protein (MCP) family are potent monocyte-macrophage chemotaxins.^{51,52} The selectin family of adhesion receptors mediates the initial tethering of monocytes to endothelial cells.¹⁸ Firm adhesion to the endothelium involves the interactions of β_1 and β_2 integrins on monocytes with the endothelial adhesion molecules ICAM-1 and VCAM-1.¹⁸

Phagocytosis

Phagocytosis involves the IgG receptor (Fc γ R) and the receptor for the complement factor C3b. Terminal sugar patterns on microbial surfaces also allow recognition by macrophages for nonspecific

phagocytosis through the mannose lectin pathway.²² However, phagosomal maturation differs from that which occurs in the neutrophil. Monocytes and macrophages have an endocytic pathway targeting the phagosome to a lysosome.²⁴ After endocytosis of a receptor–ligand complex, the contents of a vesicle are targeted to an early endosome; the ligand and receptor dissociate, and the receptor is then recycled to the cell surface.²⁴ This early endosome undergoes a series of maturation steps in which it is acidified (pH 5.5 to 6.0). This acidification is requisite for optimal protease and hydrolase activity involved in pathogen killing. It may also be integral for phagosome maturation as titrating the acidity inhibits phagosome–lysosome fusion.²⁴ Ultimately, the endosome fuses with a lysosome, which is characterized by its extreme acidity (pH <5.0) and elevated concentration of proteases.²⁴ Lysosomes are the terminal destination of phagocytosed material targeted for degradation.

After fusion, MPO released into phagosomes can react with hydrogen and halides to yield toxic hypohalous acids, superoxide anion, hydrogen peroxide, and hydroxyl radical (Table 7-3). Macrophages may also use peroxidase generated by adjacent neutrophils, eosinophils, and monocytes and acquired through endocytosis to generate these ROS. In addition to supporting the inflammatory response, macrophages also play an important immunoregulatory role in inflammation by scavenging apoptotic neutrophils at sites of inflammation.³⁹

Activation

IFN γ derived primarily from T cells is the primary activator of macrophages.^{4,50,53} Optimal macrophage activation requires both interferon IFN γ and a sensitizing agent, both of which can be provided by activated T lymphocytes. CD40 ligand on T cells can bind CD40 on macrophages to sensitize the cell. Alternatively, membrane-associated TNF α or lymphotoxin from lymphocytes can activate macrophage TNF α synthesis and thereby sensitize the macrophage to IFN γ .³⁹ IL-10 promotes monocyte maturation and macrophage differentiation.⁵⁴ Other activators include GM-CSF, TNF α , IL-1, and LPS.

Activated monocytes and macrophages can produce approximately 100 different products, including GM-CSF, M-CSF, G-CSF, IL-1, TNF α , G-CSF, and NO.^{39,55} Mononuclear phagocytes are important sources of chemoattractants such as IL-8, PAF, and leukotriene B₄ (LTB₄) that recruit neutrophils and other leukocytes. Their release of HMGB1 and other DAMP molecules serves as an endogenous “danger” signals to other immune cells in the local environment. These bind to various PRR to alter cell function. However, systemic release of HMGB1 may also be causally related to mortality in such inflammatory states as sepsis and trauma.^{56,57} The respiratory burst and subsequent production of toxic ROS mirrors that of neutrophils.

Antigen Presentation

T cells recognize only those antigens associated with surface major histocompatibility complex (MHC) molecules. MHC class I molecules are expressed on all nucleated cells, whereas MHC class II molecules are restricted to APC. After phagocytosing pathogen, mononuclear cells process and display antigen to T cells, and in doing so, initiate the development of the adaptive response (i.e., antibody formation). There is evidence that the HSP receptor CD91 may also participate in this process (see below). This processed antigen is presented on the APC cell surface in the context of MHC molecules that are specifically recognized by T-cell receptors (TCRs) and essential for T-cell activation. CD4⁺ T cells, or helper T cells (T_H), recognize antigen coexpressed with MHC class II molecules and induce B-cell differentiation into either memory or antigen-specific antibody-producing plasma cells. These T_H cells can also induce macrophage production of NO, ROS, and other inflammatory mediators. CD8⁺ cytotoxic T lymphocytes (CTL) recognize antigen in the context of MHC class I molecules and induce target cell lysis; they destroy host cells infected with intracellular pathogens or cells of malignant potential.⁵⁸ Activated mononuclear phagocytes release IL-12, a potent stimulus for T_H cells and the production of inflammatory cytokines, and elaborate IL-15, the function of which mirrors that of IL-2.^{59,60}

The three professional APC are DCs, macrophages, and B cells. DCs are a specialized APC, which process and present antigen to naïve T cells. Monocytes stimulated with GM-CSF, IL-4, or IL-13 differentiate toward DC. Maturation of the DC requires TNF α or LPS stimulation.³⁹ Epidermal Langerhans cells, after encountering antigen, migrate through the lymphoid organs and differentiate into mature DC. DC cells are particularly effective at presenting viral antigen. They present antigen in the context of both MHC I and MHC II, and thereby induce both a T_H1 and a T_H2 response, respectively. DC can also present antigens derived from apoptotic cells in the context of MHC I.^{61–63}

Macrophages present antigenic peptides from ingested pathogens that persist in the phagosomes. These peptides, usually of bacterial origin, are expressed in conjunction with MHC II molecules. B cells,

by contrast, bind specific soluble molecules (insect toxins, venom, and allergens) via immunoglobulin. This is endocytosed, processed, and presented on surface MHC II.^{39,63–65}

Lymphocytes

B, T, and NK cells comprise this lineage of inflammatory cells (Table 7-1). B and T cells are central to the adaptive immune response, whereas NK cells lack antigen specificity and primarily function during innate immune response. NK cells are the first line of defense against many viral infections. The loss of surface expression of MHC class I molecules as occurs with virus-infected cells serves as a target for NK cells.^{39,66} Alternatively, NK cells bind cell-bound antibody and participate in antibody-dependent cell cytotoxicity. Cells targeted by either mechanism are induced to undergo cell death.

B Lymphocytes

B cells, though of bone marrow origin, attain full maturation within extramedullary sites such as lymph nodes, the spleen, and the mucosal lymph nodules of tonsils and Peyer patches. With activation, B cells differentiate into antibody-producing plasma cells, which through the elaboration of antibody, aid the neutralization of viruses and bacterial toxins, and facilitate opsonization for phagocytosis and complement activation.⁴ Activation requires antigen binding to cell surface receptors and stimulation by T_H cell–derived cytokines; they do not need the assistance of APCs. Polyclonal B-cell activation can occur in a T-cell–independent mechanism if the antigen has a large repeating polymeric sequence.^{39,67}

T Lymphocytes

Development of T lymphocytes begins within the marrow and is completed in the thymus. The final population profile is determined by apoptotic processes of both positive and negative selection.⁶⁸ Any protein or antigen of *host* origin is presented by APCs, and thymocytes reactive to these self-proteins are deleted.⁶⁹ Alternatively, expansion of cell lines recognizing foreign, or rather nonself antigen, occurs through positive selection. IL-7 provides the stimulation for proliferation and differentiation of developing T cells. Ultimately, two lines of mature cells, $CD4^+$ and $CD8^+$, will develop.⁶⁹

Lymphocytes, the smallest of the leukocytes, constitute approximately 20% of circulating leukocytes.⁴ Most circulating lymphocytes are T cells, and 60% of those are $CD4^+$, a marker of a T_H phenotype. The other 40% are $CD8^+$, called cytotoxic T cells, T_C . The normal ratio of $CD4^+/CD8^+$ is 2:1.⁴ Lymphocytes continuously recirculate through lymph nodes, spleen, lymphatics, lymph nodules, and blood, providing continuous surveillance. Encounter with a particular antigen initiates activation toward an effector T cell. Activation of a T cell requires bind to its specific antigen plus a costimulatory signal provided by the interaction between costimulatory molecules on the APC and their cognate receptors on the T cell.³⁹

Naïve T cells circulate continuously between blood and lymphoid organs, making contact with many APCs and the epitopes of the antigens they express.⁷⁰ Initially, lymphocytes enter the cortical region of lymph nodes by migrating across the high endothelial venules, a process mediated by the selectin family of receptors. L-selectin, which is found constitutively on all lymphocytes, binds sialyl Lewis carbohydrate on the endothelium.³⁹ For example, L-selectin on lymphocytes binds GlyCAM-1 on the high endothelial venules in lymph nodes. In mucosal tissues, L-selectin and endothelial MAdCAM-1 guide emigration. Migration across the endothelium requires integrins, in particular LFA-1 and its interaction with ICAM-1 and ICAM-2 on endothelial cells.⁷¹ Most lymphocytes are carried back to the blood by the efferent lymphatics. If a T lymphocyte recognizes its specific antigen on the surface of an APC, it remains for several days, then returns to the blood as an armed effector T cell.³⁹

Adhesion molecules mediate many of the transient interactions between T cells and APCs that are required for the T cell to sample each antigen it encounters. Lymphocyte LFA-1 can bind the APC in a loose, reversible fashion by any of the ICAM molecules on APCs. If a match between T cell and antigen is found, conformational changes in LFA-1 greatly increase its affinity for ICAM-1 and ICAM-2 to stabilize the interaction. The T cell can then proliferate and differentiate into an effector cell. Effector T cells lose surface expression of L-selectin and no longer circulate through lymphoid tissue. Instead they express VLA-4, an integrin, which binds vascular endothelium at sites of infection, and the cell is retained at the focus. Effector T cells have increased LFA-1 and CD2 adhesion molecule expression that facilitate tight binding to target cell.^{72,73}

Antigen binding in the appropriate context provides the signal for clonal expansion and differentiation of T cells into effector and memory lymphocytes. The appropriate contact is composed of antigen complexed with MHC class II molecules on APCs, costimulators, and cytokines produced by the APCs and by the T cells themselves. This first encounter of naïve T cells with antigen is the primary immune

response, which serves to induce the formation of effector and memory T cells. These activated T cells hone to peripheral tissues where, upon reexposure to their specific antigen, they activate macrophages to eliminate phagocytosed microbes and induce B-cell differentiation and antigen-specific antibody secretion. The CD8⁺ CTLs kill infected host cells and tumor cells that display class I MHC-associated antigen. Naïve T cells require activation by DCs, whereas effector T cells can respond to antigens presented by a wider variety of APCs, such as macrophages and B lymphocytes. Not surprisingly, differentiated effector and memory T cells possess lower thresholds for costimulation and require lower antigen concentration for activation than naïve T cells.

In general, antigen presented on MHC II molecules is the prototypical stimulus for CD4⁺ T-cell activation and the subsequent production of a variety of cytokine mediators, including IL-2, which stimulate further expansion and activation. However, the circumstances under which this activation occurs may dictate disparate paths of differentiation, producing T-cell subsets with distinct cytokine profiles and effector functions. These differing phenotypes have been utilized to characterize two distinct subsets: T_H1 and T_H2.^{59,60,74} IL-12 derived from phagocytes infected with intracellular pathogen provides the necessary signal for T_H1 differentiation.³⁹ IL-12 also stimulates production of IFN γ , the principle macrophage activator, by NK cells and CD4⁺ lymphocytes. Interferons stimulate T_H1 development by augmenting phagocytic IL-12 production and by maintaining IL-12 receptor expression on CD4⁺ T cells. The principal effector action of T_H1 cells is the activation of macrophages through the production of IFN γ , GM-CSF, TNF α , CD40L, and FasL.^{39,59,60,74} They regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses. This inflammatory response, also referred to as cell-mediated immunity or delayed-type hypersensitivity, provides one major arm of the adaptive immune response; it is mediated by CD4⁺ and CD8⁺ lymphocytes and macrophages.

The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils.^{59,60,74} These cells are the cellular effectors of humoral immunity and provide the other major arm of the adaptive immune response, which is mediated by T_H2 CD4⁺ cells, B cells, plasma cells, and antibodies. They produce IL-4, IL-5 and CD40L, thereby inducing B-cell activation and antibody production, and a host of other proinflammatory and anti-inflammatory cytokines.³⁹ Activation of mast cells and eosinophils by extracellular pathogens is associated with activation of T_H2 cells. T_H2 cells quell the inflammatory response by inhibiting macrophage functions and T_H1 responses. They are considered the anti-inflammatory arm of cell-mediated inflammation. Helper T cells that express both T_H1 and T_H2 patterns of cytokine expression have been called T_H0 cells, and further studies will certainly discern other subsets of T cells.^{4,74}

T-cell activation, differentiation, and expansion are orchestrated by the T cell itself. The responding T cell, in an autocrine fashion, serves as both source and target of a variety of mediators stimulating growth. The principal autocrine growth factor is IL-2, which is induced by signaling regulated by the phosphatase calcineurin (see below).⁷⁵ IL-15 stimulates the proliferation of CD8⁺ T cells, especially memory cells of the CD8⁺ subset. After antigen exposure, the numbers of T cells specific for that antigen may increase to about 1 in 10 for CD8⁺ and 1 in 1000 to 10000 for CD4⁺ cells.⁴

After activation, some proliferating T cells will differentiate into effector cells that eliminate antigens and activate other immune cells. Mature CD4⁺ cells induce the activation of mononuclear phagocytes and B cells. CD8⁺ cells differentiate into CTL that recognize viral and other intracellular pathogen antigens that are presented in the context of MHC class I molecules and induce target cell death by releasing the cytotoxins perforin and granzymes from cytoplasmic granules. Granzymes are serine proteases that trigger DNA fragmentation and apoptosis. Perforin stimulates cell membrane pore formation that facilitates granzyme entrance into cells. Apoptosis can also be induced by the binding of Fas ligand on CTL to Fas on the target cell. CTLs also release the cytokines IFN γ , TNF α , and CC chemokines. IFN γ and certain CC chemokines have antiviral properties, and both are potent activators of macrophage function. IL-2 produced by CTL and local helper CD4⁺ lymphocytes expands the CTL, and IL-12 released by APC stimulates CTL activity. As with CD4⁺ cells, early evidence suggests that the population CD8⁺ may be divided into T_C1 and T_C2 cells based on their cytokine profiles and effector functions.^{39,58–60}

Other T cells will mature into long-lived functionally quiescent memory cells. Upon antigen reexposure, a cell surface rich in adhesion molecules (i.e., integrins, CD44) facilitates rapid and efficient migration to peripheral sites of infection.⁴ These cells accumulate over time and in the adult human comprise more than half of the circulating T cells.

Mere antigen exposure is insufficient for activation of naïve T cells. Proliferation and differentiation require costimulatory signals provided by molecules on APCs. The best characterized costimulator pathway involves the T-cell surface molecule CD28 and its counterligands B7-1 and B7-2 expressed on activated APCs.^{4,39} CD28 delivers signals that enhance T-cell survival, by increasing expression of the antiapoptotic protein Bcl-X, the production of cytokines such as IL-2 and the IL-2 receptor, and the differentiation of immature T cells. In vitro, purified populations of CD4⁺ cells challenged with antigen by APCs that express B7, proliferate and secrete cytokines. This does not occur if B7 is absent. The costimulatory signal must come from the same APC that provides the initial signal. DCs are the most potent APC because they express both classes of MHC molecules and the B7 molecules, whereas macrophages and B cells must be activated to express the costimulatory molecules. This expression of costimulators is regulated so as to ensure that T-cell activation is temporally and spatially appropriate. For instance, during T-cell activation, engagement of CD40 ligand with CD40 induces upregulation of B7 costimulators on the APCs. In addition, it increases the secretion of cytokines such as IL-12 that promote T-cell differentiation, and cytokines are secreted that promote T-cell differentiation and activation. A protein CTLA-4, expressed on activated T cells, is homologous to CD28 and binds B7-1 and B7-2. Unlike CD28, CTLA-4 functions to terminate T-cell responses and plays a role in self-tolerance. On the basis of many experimental studies of costimulators, antagonists against B7 molecules and CD40L are in clinical trials to prevent the rejection of organ allografts.^{4,39}

The differentiation of naïve CD8⁺ T cells to CTL requires a stronger costimulatory signal. This can be provided by either DC, as they have the greatest intrinsic costimulatory activity, or by a CD4⁺ helper T lymphocyte. Naïve helper T cells attached to the same APC as the CD8⁺ T cell can be activated to elaborate IL-2. Attached effector T helper cells can stimulate the APC to express more costimulatory molecules. In the case of virulent viruses, cytotoxicity can substitute for CD28 costimulation, and so the typical costimulatory signal is not required for activation. For less virulent viruses, costimulation is necessary for CTL induction.^{39,76} The absence of costimulation results in an unresponsive, or anergic T cell. Recently this has been shown to be mediated by the serine/threonine kinase calcium/calmodulin-dependent protein kinase (CaMK) II (see below).⁷⁷ Anergic T cells do not produce IL-2 and therefore cannot proliferate and differentiate into effector cells even when presented with antigen at a later time.³⁹

The affinity of most TCRs for peptide–MHC complexes is low, with dissociation constants of the order of 10^{-5} to 10^{-7} and an estimated TCR–antigen interaction of less than 10 seconds. Furthermore, on any APC fewer than 1000 of the 10^5 available MHC molecules are likely to be displaying any one peptide at any particular time. Therefore, one APC can engage a small fraction of the 10^4 to 10^5 antigen receptors on a single T cell.⁴ Activation of an individual T cell may require multiple sequential engagements of that cell's antigen receptors by peptide–MHC complexes on APCs. With engagement, there is clustering of membrane receptors, tyrosine phosphorylation of several proteins, and recruitment and activation of adaptor proteins.

TCRs are devoid of enzymatic activity and must utilize other signal-transducing proteins.⁴ After TCR–MHC engagement, several membrane surface proteins and intracellular signaling proteins are rapidly recruited: TCR complex, CD4 or CD8, receptors for costimulators such as CD28, and enzymes and adaptor proteins.⁴ After TCR clustering, activated tyrosine kinases associated with and phosphorylate tyrosine residues on CD3 and TCR (Fig. 7-5). These phosphorylation sites provide docking sites for other tyrosine and protein kinases, such as Lck, an Src family tyrosine kinase, and ZAP-70, a tyrosine kinase. These kinases become activated with phosphorylation. Activated ZAP-70 phosphorylates several adaptor proteins that subsequently induce a variety of signal transduction cascades. Adaptor proteins contain structural domains that bind other proteins and thereby facilitate the correct spatial orientation that is required for signal transduction. The ras pathway is also activated, which is an early step in the activation of the mitogen-activated protein kinases (MAPK) that can activate a variety of transcription factors. Ras is a member of a family of guanine nucleotide-binding proteins (GDP/GTP) that are involved in diverse activation responses in different cell types. This pathway is an amplification process by which few upstream kinases lead to the activation of several downstream kinases. Ultimately activation of the terminal extracellular regulated kinase (ERK 1/2) leads to the phosphorylation of the protein ELK, which stimulates the transcription of fos, a component of the activation protein 1 (AP-1) transcription factor (Table 7-4). Concomitantly, c-Jun N-terminal kinase (JNK) is activated, which phosphorylates c-Jun, the second component of AP-1. The third member of the MAPK family, p38, is also activated. The activities of the MAPKs are terminated by specific protein tyrosine/threonine phosphatases that are regulated by the MAPKs themselves. Hence, the entire system is self-regulated by

a negative feedback system.⁴

Figure 7-5. T-cell signaling and activation. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

Table 7-4 Transcription Factors

Transcription Factor	Stimuli	Effector Genes
AP-1	TNF, IL-1, UV light, H ₂ O ₂ , LPS, stress, ROS, hypoxia	TNF, IL-1, IL-2, IL-5, IFN-γ, ICAM-1, E-selectin, GM-CSF, MMPs, COX-2
NFκB	TNF-IL-1, UV light, H ₂ O ₂ , LPS, ROS	IL-1, IL-2, IL-6, IL-8, IL-12, TNF, E-selectin, VCAM-1, ICAM-1, MIP-1, MCP-1, RANTES, iNOS, cotaxin, PLA ₂ , G-CSF, GM-CSF, IFN-β
STAT	IFNs, CSFs, GFs, IL-1 to IL-15	FOS, E-selectin, Myc, ICAM-1, FcγRI
NFAT	TCR, BCR, FcεR, FcγR, histamine and thrombin receptors	IL-2, IL-3, IL-4, IL-5, IL-8, IL-13, TNF, GM-CSF, IFN-γ, CD40L, FASL

AP, activator protein; CSF, colony-stimulating factor; COX, cyclooxygenase; GF, growth factor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; iNOS, inducible nitric oxide synthase; LPS, lipopolysaccharide; MMP, matrix metalloproteinase; MPO, myeloperoxidase; NFAT, nuclear factor of activated T cells; NFκB, nuclear factor kappa-B; PLA₂, phospholipase A₂; ROS, reactive oxygen species; STAT, signal transducer and activator of transcription; TNF, tumor necrosis factor; UV, ultraviolet; VCAM, vascular cell adhesion molecule.
 Modified from Gallin JI, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 1999.

Activation of TCR also leads to the induction of PLC, in particular PLCγ1 (Fig. 7-5). Phosphorylated PLCγ1 catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP₂) into inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG), and activates enzymes that generate additional active transcription factors. IP₃ increases cytosolic calcium that leads to a large influx of both intracellular and extracellular calcium with subsequent activation of calcium- and calmodulin-dependent proteins. Calcineurin, a calcium/calmodulin-dependent phosphatase is integral to T-cell activation via modulation of the activation of the transcription factors nuclear factor of activated T cells (NFAT) and NFκB (Table 7-4).^{4,75} These transcription factors are essential for the induction of cytokine transcription, in particular IL-2 production. However, in the absence of costimulation, activation of the CaMK II opposes the actions of calcineurin as described above and produces an anergic cell.⁷⁷ DAG activates protein kinase C, which activates additional transcription factors. The role of PKC and calcium in T-cell function is made evident by studies in which pharmacologic activation of PKC and/or elevation of intracellular calcium concentration stimulates T-cell cytokine secretion and proliferation.⁴ Regulation of those kinases operant in T-cell signaling involves protein tyrosine phosphatases. Through dephosphorylation they modulate TCR signaling. Two phosphatases induced with TCR clustering are SHP-1 and SHP-2.

The ultimate goal of all these signaling transduction pathways is to activate transcription factors that bind to promoter regions and enhance transcription. Three transcription factors that are activated in T cells and appear critical for most T-cell responses are NFAT, AP-1, and NFκB (Table 7-4).

A third mechanism of T-cell activation involves lipid antigens, such as cell wall protein from intracellular bacteria. These antigens bind CD1, a MHC-related cell surface molecule that presents these

antigens to certain subtypes of T cells. A superantigen is an unprocessed bacterial or retroviral product that binds the MHC molecule and the TCR outside the usual antigen-binding sites. This engagement leads to a polyclonal and nonspecific stimulation of a large proportion of the T-cell population. An overwhelming activation of all arms of the immune system ensues and underlies much of the pathophysiology of toxic shock syndrome (TSS). Intravenous immunoglobulin (IVIG), by binding this antigen, is thought to be of therapeutic benefit.

Eosinophils

Eosinophils are marrow-derived granulocytes that share some properties of neutrophils, act in conjunction with basophils and mast cells as primary effectors in allergen inflammation and are involved in the eradication of helminthic infections (Table 7-1). Upon exiting the marrow, their intravascular half-life is but a few hours, whereafter they enter the mucosa of the lung, gastrointestinal, and genitourinary tracts.^{39,78} IL-3, GM-CSF, and IL-5 promote eosinophil differentiation, the induction of effector functions, and survival, the last by inhibiting apoptosis.⁷⁸ Emigrating through inflamed endothelium they release inflammatory mediators and toxic agents from cytoplasmic granules. They generate superoxide anion and hydrogen peroxide, though less efficiently than neutrophils. They express IgE receptors and stimulate histamine release from basophils and mast cells through major basic protein (MBP). They can also regulate basophil and mast cell function by releasing enzymes that inactivate histamine and slow-reacting substance of anaphylaxis (SRS-A).

Recruitment and Activation

Eosinophils are recruited primarily to sites of parasitic infection and allergen challenge. Mast cells and macrophages responding to either secrete mediators (IL-5, PAF, LTB-4) that upregulate expression of endothelial adhesion molecules. Eosinophils themselves are more responsive to CC chemokines (MIP-1 α , RANTES, and MCP-3) and the cytokines produced with T_H2 activation. Engagement of eosinophil β_1 integrin VLA₄ with VCAM-1 and fibronectin on the endothelium initiates the process of emigration. IL-4 can activate both the binding and the upregulation of endothelial cell VCAM-1. Diapedesis and tissue infiltration also involves members of the β_2 integrin family (Mac-1 and LFA) similar to that which mediates neutrophil recruitment.^{39,79}

Eosinophils are activated by IL-3, GM-CSF, IL-5, PAF, CC chemokines, and C3a and C5a of complement. IL-5 is a potent activating agent and enhances the ability of eosinophils to release granule contents on FcR cross-linking. A positive feedback cycle ultimately is established, in which recruited eosinophils produce cytokines and chemokines that recruit more eosinophils and other leukocytes.

Granules

Eosinophils possess a compartmentalized armamentarium of toxic substances that assist in the elimination of organisms, in particular helminths. Their specific granules contain GM-CSF and MBP, the latter of which is cytotoxic to parasites and normal cells. Further, it functions as a stimulus for histamine release from mast cells and basophils.⁸⁰ The granule matrix contains eosinophil peroxidase (EPO), eosinophil-derived neurotoxin, lysosomal enzymes, catalase, TNF α , TGF β , and eosinophilic cationic proteins that stimulate formation of transmembrane pores to increase target cellular permeability.⁸¹ EPO is released extracellularly on target cell surfaces where it generates hydrogen peroxide and hydrogen halides. Approximately 30% of oxygen consumed by stimulated eosinophils is utilized in the formation of halogenating species. Thiocyanate may be the major halide for the EPO–H₂O₂ system.⁸² If ingested by a neighboring phagocyte, EPO can combine with H₂O₂ and halides to form hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. Although they express Fc receptors for IgG, IgA, and IgE, they are relatively insensitive to activation by antigen-mediated cross-linking of these receptors. However, they can kill microorganisms by antibody-dependent cell-mediated cytotoxicity.^{4,39}

The primary targets of eosinophils are extracellular parasites. The size of these pathogens prohibits phagocytosis, and their integument is relatively resistant to the microbicidal products of neutrophils and macrophages; however they can be killed by MBP, which is released after cross-linking of Fc-bound IgE coating the parasite. The T_H2 response to parasitic invasion produces IL-4, IL-5, and IL-13. IL-4 stimulates the production of specific IgE antibodies, which opsonize helminths. IL-5 activates eosinophils, which bind to the IgE-coated helminths via Fc receptors. Activated eosinophils then release their granule contents and generate ROS and hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. The sparse uncompartmental granules contain Charcot–

Leyden crystals and have lysophospholipase activity. Finally, eosinophils produce and release lipid mediators such as PAF, prostaglandins, and LTs, which probably contribute to the process of allergic diseases.^{4,83,84}

Basophils and Mast Cells

Basophils and mast cells are central to the development of allergic inflammation and produce cytokines, lipid mediators, vasoactive amines, and proteases that can also participate in nonallergic inflammatory responses (Table 7-1). Both cells share a common progenitor cell, which diverges early during differentiation. The primary growth factors for basophil development are IL-3 and GM-CSF, whereas stem cell factor is the primary stimulus for mast cell maturation.⁸⁵ Although basophils and mast cells are distinct cell types, they are often grouped together because of the similarity of their granule content, the stimuli inducing activation, and their effector functions.³⁹

Mature basophils constitute only 0.5% to 1% of the circulating leukocytes. Mast cells are primarily tissue-fixed residents of connective tissue. Engagement of IgE-bound antigen with the high-affinity IgE antibody receptor, FcεR, provides the primary stimulus for basophil and mast cell activation and degranulation. In addition, diverse agents such as contrast media, opiates, anaphylatoxins, chemokines, and neuropeptides may serve as activators. Basophils and mast cells elaborate both preformed, as well as, newly synthesized inflammatory mediators. The main basophil proteoglycan is chondroitin sulfate A, whereas mast cells contain heparin, chondroitin sulfate, and chondroitin sulfate E and also store neutral proteases.⁸⁶ The lipid mediators LTB₄, LTC₄, and PGD₂ are synthesized de novo in response to stimulation. The LTs are powerful vasoconstrictors, bronchoconstrictors, and chemoattractants for neutrophils and eosinophils. PGD₂ inhibits platelet aggregation and is chemotactic for neutrophils. Both basophils and mast cells synthesize and secrete histamine. Histamine, or 2-(4-imidazolyl)-ethylamine, is formed by the carboxylation of histidine. It is stored in preformed granules at acid pH as a complex with proteins and proteoglycans. Mast cells carry greater quantities of histamine than do basophils. The classic vasoactive properties of arteriolar dilatation, increased vascular permeability, and bronchoconstriction are mediated by the H₁ receptors. H₂ receptors are involved in modulation of the immune response and stimulating gastric output and mucus secretion. H₃ receptors participate in neuroconduction.^{39,86,87}

Platelets

Though classically considered in the context of hemostasis, studies confirm that platelets are also integral to normal and pathologic inflammation and link the processes of hemostasis, inflammation, and tissue repair. They are activated in a variety of inflammatory conditions, such as rheumatoid arthritis and inflammatory bowel disease, a testimony to their role in inflammation.⁸⁸ Upon activation, they release factors that enhance vascular permeability, chemokines, microbicidal proteins, and mitogens for endothelial cells, smooth muscle cells, and fibroblasts. They assist leukocytes in promoting the inflammatory reaction and killing microbes by providing an adhesive surface to facilitate emigration, by stimulating adhered leukocytes, and by further modulating chemokine synthesis (Table 7-5).^{88,89}

Humans possess about $150 \text{ to } 400 \times 10^9$ platelets per liter of blood.⁸⁸ Thrombopoiesis is regulated by thrombopoietin as well as a variety of other mediators (IL-3, IL-4, IL-6, IL-7, and IL-11). In fact, human IL-11 is in clinical use to stimulate thrombopoiesis in patients undergoing chemotherapy.⁹⁰ After release from the marrow, platelets circulate with a half-life of approximately 12 days. Interferon α is inhibitory for megakaryocyte growth, and the elevated levels induced with some viral and inflammatory conditions may explain the relative thrombocytopenia observed in these conditions.^{88,91}

Recruitment and Activation

Platelets are activated by and aggregate in response to thrombin or activated endothelium. Clot formation triggers the release of vasoactive agents (PGE₂, PGI₂, PGF₂α, and platelet-derived growth factor [PDGF]) and inflammatory mediators. Serotonin, PGE₂, and PAF increase vascular permeability. The adhesion molecule PECAM-1 and the β₃ integrins mediate platelet plug formation, endothelial cell adhesion, and leukocyte emigration. The integrin IIb/IIIa and P-selectin facilitate platelet interactions with other inflammatory cells. The α granules are rich in membrane-bound P-selectin; upon fusion with the cell surface membrane they enhance the cell surface density of this receptor. On stimulation, both receptors are expressed on the platelet surface in an activated state. IIb/IIIa binds various adhesive proteins containing the RGD sequence (i.e., fibrinogen), which serve as a mechanical link to other

platelets, leukocytes, and the endothelium. Possibly, the immobilization of activated P-selectin-expressing platelets on the vessel wall may biochemically and functionally promote the adhesion of neutrophils to endothelial cells.^{88,91}

Adapted from Klinger MHF, Jelkmann W. Role of blood platelet in infection and inflammation. *J Interferon Cytokine Res* 2002;22:913–922.

Platelets are a primary source of chemoattractants for neutrophils. Neutral proteinases released from stimulated platelets cleave complement factor C5, liberating the chemoattractant C5a. PDGF binds strongly to the extracellular matrix, providing a long-acting source of chemoattractant. Platelet factor 4 (PF4) is a cationic protein that penetrates the vascular wall and is a chemoattractant. Activated platelets also bind monocytes via P-selectin and PSGL-1 and induce the expression and secretion of monocyte chemotactic protein-1 (MCP-1) and IL-8. Thrombospondin released from activated platelets mediates monocyte binding to platelets. Together these substances promote leukocyte margination, activation, and recruitment to the sites of injury.³⁹

Granules

The vasoactive substances and inflammatory mediators of platelets are either stored in cytoplasmic granules or synthesized de novo. A platelet contains about 35 *α granules* and 5 *dense bodies*. The dense granules contain adenosine diphosphate (ADP), ATP, serotonin, and calcium that are required during the earlier stages of inflammation. ADP is the principal platelet agonist during platelet aggregation and augments the oxidative burst of neutrophils. Serotonin increases vascular permeability and enhances the superoxide production by macrophages.⁸⁸

The more abundant α granules contain fibrinogen, RANTES, MIP-1α, thrombospondin, P-selectin, PF4, PDGF, TGFβ, β-thromboglobulin, high-molecular-weight kininogen (HMWK), and many other biologically active proteins. PF4 and β-thromboglobulin initiate leukocyte recruitment and activation. PF4 induces neutrophil adherence to unstimulated endothelium and the release of secondary granules. It inhibits monocyte apoptosis and promotes macrophage differentiation. PF4 can also stimulate histamine release from basophils. RANTES is deposited on the endothelium and recruits monocytes from the circulation. PAF induces platelet aggregation, increases vascular permeability, enhances phagocyte free radical formation, and the adhesion of platelets to neutrophils. Platelet activation appears to occur in

allergic asthma and may precede the delayed accumulation of eosinophils in the lung after allergen exposure. The α granules also carry several important growth factors, including vascular endothelial growth factor (VEGF), PDGF, and TGF β . VEGF promotes extravasation and aids recruitment of leukocytes. PDGF is chemotactic for neutrophils and monocytes. TGF β is chemotactic for and activates neutrophils and monocytes early during inflammation, but displays immunosuppressive effects during later stages of inflammation.⁸⁸

Platelets are an important source of eicosanoids, including thromboxane, prostaglandins F₂ α and E₂. Thromboxane synthetase in platelets is responsible for the production of TXA₂, a potent vasoconstrictor that also increases vascular permeability and stimulates platelet aggregation. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit platelet function by inhibiting TXA₂ production. As this effect is irreversible, new platelets must be produced (7 to 10 days) to restore normal clot formation. In emergent circumstances (management of intracranial hemorrhage) platelet administration is required. Recently, an aspirin response test has been developed that assists in guiding therapy and targeting transfusion to those with functional evidence of platelet inhibition. It has also assisted in monitoring the response to transfusion. PGF₂ α causes vasoconstriction, whereas PGE₂ vasodilates and modulates pain.^{92,93}

Platelets participate in transcellular lipoxygenase (LO) metabolism, which refers to the production of eicosanoids through interactions with neighboring inflammatory cells. Endothelial cells utilize platelet-derived endoperoxides to synthesize PGI₂. Platelets interact with neutrophils in several pathways, providing a direct link between thrombosis and inflammation. 12-hydroxyeicosatetraenoic acid (12-HETE) released from activated platelets can be used by unstimulated neutrophils to produce the chemoattractant 12,20-HETE. 12-HETE and 5-HETE from activated platelets and neutrophils, respectively, can combine in either cell type to form 5,12 diHETE, an anti-inflammatory compound, which diverts production away from the proinflammatory LTs. 12-LO from platelets and LTA₄ formed by neutrophils can produce the intermediate 5(6)-epoxytetraene. This intermediate produces lipoxins A₄ and B₄ that have primarily counterinflammatory functions.^{39,89,92,94}

In addition to modulating inflammation platelets possess some direct microbicidal activity. Platelets are activated and degranulate when exposed to certain bacteria. Electron microscopic studies have shown that activated platelets internalize bacteria and viruses. The α granules contain antibacterial proteins called thrombocidins (TC) in humans that support the killing of adherent bacteria. The two antibacterial proteins isolated from human platelets (TC-1, TC-2) are bactericidal for *Escherichia coli* and *S. aureus*.⁸⁸

NONCELLULAR COMPONENTS

Cytokines

Cytokines are soluble protein mediators secreted by the cells of the innate and adaptive immunity in response to microbes and other antigens, including intra- and extracellular proteins, and mediate many of the functions of these cells (Table 7-6). They regulate and influence the host response to both PAMPs on bacterial, viruses, fungi, and parasites and DAMPs released during trauma, burns, allograft rejection, ischemia/reperfusion injury, and autoimmune disease. They govern lymphocyte differentiation during adaptive immunity and activate effector cells of both arms of inflammation to eliminate microbes. Cytokines play important roles in tumor biology and angiogenesis. Though essential for a normal immune response, excessive cytokine release underlies a variety of pathophysiological inflammatory states such as ARDS and MODS.⁹⁵⁻⁹⁸

Table 7-6 Cytokines

Cytokine	Receptor	Signal Transduction	Cellular Source	Targets	Effects
TNF α	TNF R	TRAFs Death domains	Mo/M ϕ , MC, Ba, Eo, NK, B, T, F, Ep	Endothe- lium PMN Many cells	$\uparrow$ inflammation, coagulation, adhesion molecules $\uparrow$ activation $\uparrow$ apoptosis $\uparrow$ fever, APP, catabolism

IL-13	Type I	JAK/STAT		Mo/M ϕ B EC	$\downarrow$ M ϕ function switching to isotype IgE $\uparrow$ adhesion molecules and CC chemokines

APP, acute-phase protein; B, B cell; Ba, basophil; EC, endothelial cell; Ep, epithelial cell; F, fibroblast; IL, interleukin; IRAK, IL-1R-associated kinase; JAK/STAT, Janus kinase/signal transducer and activator of transcription; MC, mast cell; MHC, major histocompatibility complex; Mo, monocyte; M ϕ , macrophage; NK, natural killer; PMN, polymorphonuclear leukocyte; T, T cell; TNF, tumor necrosis factor; TRAF, tumor necrosis factor receptor-associated factor.

Modified from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders 2003:179; 181–182.

Cytokine secretion is brief, and as cytokines typically are not stored preformed, they must be transcribed and synthesized de novo synthesis, which is also transient as the messenger RNA is unstable.

Their functions are pleiotropic and redundant, which has been interpreted to represent a teleological safety mechanism. However, such protective characteristics greatly limit the therapeutic utility of either cytokine administration or blockade. In fact, over 30 randomized controlled clinical trials have been conducted to assess the efficacy of modulating inflammation, on reducing mortality in a variety of contexts: trauma, sepsis. The majority have involved manipulating systemic cytokine concentrations. Only one, activated protein C, was briefly FDA approved for use; it was recently removed from the market due to lack of benefit.⁹⁹

Cytokines often influence the synthesis and actions of other cytokines, such as IL-1–induced T-cell IL-2 production; this interaction may be synergistic (additive or multiplicative) or antagonistic. They may function in an autocrine, paracrine, or even endocrine function, although the inability to correlate plasma cytokine concentrations with the extent of tissue damage suggests that they are designed for local rather than systemic inflammation.^{4,39,95}

Cytokine actions are mediated by specific membrane receptors on target cells to which they bind with high affinity ($K_D \propto 10^{-10}$ to 10^{-12}). Hence, only minute quantities are necessary to elicit a response. Such efficiency is accompanied by a narrow therapeutic index and potential for unwanted global effects (i.e., MODS) with even small systemic concentrations. The receptors and the cells expressing them are regulated by external stimuli, which provide some degree of specificity to the response, even though the cytokines themselves are not antigen specific. Receptor binding alters cellular gene transcription (induction or suppression) that may result in proliferation, differentiation, and the acquisition of new or suppression/enhancement of pre-existing functions.⁴

All cytokine receptors consist of at least one transmembrane protein with an extracellular portion for ligand binding and an intracellular domain mediating signal transduction. Current receptor classification is based on structural homologies among the extracellular cytokine binding domains. Type I cytokine receptors contain a domain with two conserved pairs of cysteine residues and a membrane proximal sequence of tryptophan-serine-X-tryptophan-serine, where X is any amino acid (WSXWS). Type II resemble type I receptors, however the WSXWS motif is absent. The Ig superfamily consists of receptors with extracellular Ig domains. TNF receptors belong to a family of receptors with conserved cysteine-rich extracellular domains. Finally seven-transmembrane α -helical receptors mediate the functions of cytokines called chemokines through GTP-binding (G) proteins.⁴

Translating ligand engagement to the signaling events that alter cellular phenotype involves a variety of signaling cascades dependent upon the structure of the cytoplasmic tail of the particular receptor (Table 7-6). This is another method by which to classify cytokine receptors. These individual signaling cascades will be discussed in the context of the various cytokines and respective receptors employing them.

Early Cytokines/Innate Immunity

TNF- α

TNF α is the principal initiating mediator of the inflammatory response to gram-negative bacteria and other infectious pathogens. It is an important early mediator of inflammation and is essential for the normal initiation, maintenance, and repair of tissue injury. However, aberrant production may underlie the pathologic sequelae of many inflammatory and infectious states (i.e., MODS, rheumatoid arthritis, Crohn's disease). Mononuclear phagocytes are the principle source of TNF α , usually in response to the potent prototypical stimulus lipopolysaccharide of gram-negative organisms.^{100,101} TNF α production may be augmented by concomitant stimulation with IFN γ , IL-4 and IL-10, whereas, corticosteroids are suppressive.¹⁰² Secondary sources include mast cells, NK cells, and T and B lymphocytes. Other stimuli inducing production and release include complement C5a, GM-CSF, hypoxia, IL-1, NO, ROS, and TNF α itself.³⁹

TNF α is expressed on the cell membrane as a bioactive protein and is cleaved into its soluble form by a specific TNF α converting enzyme. There are 2 distinct TNF receptors present on virtually all cell types (Fig. 7-6).¹⁰³ Ligand binding to TNF-RII leads to recruitment of TNF receptor-associated factors (TRAFs) that ultimately activate the transcription factors NF κ B and AP-1, and thereby influence gene expression and cellular phenotype.⁴ Alternatively, binding to TNF-RI activates caspases and triggers apoptosis, in addition to signaling transcription factors. The manner by which either a proinflammatory or apoptotic path is chosen is unknown, although the net effect of TNF α binding is probably the culmination of differential adaptor protein expression and downstream signal transduction cascades. TNF-RI appears to be more important in host defense as knockout TNF-RI mice show a greater degree of impairment in host defense than mice lacking TNF-RII.⁴

Shedding of extracellular domains of the two TNF α receptors by metalloproteinases can further alter the biologic activity of TNF α by decreasing the number of cell signaling sites on target tissues and increasing the amount of circulating inhibitors. Unlike other members of the TNF family that are primarily involved in regulation of cell proliferation, TNF α has both proinflammatory and apoptosis-inducing properties.^{95,104}

Figure 7-6. TNF receptor signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

The principal function of TNF α is to recruit neutrophils and monocytes to foci of infections and to activate these cells to eradicate microbes. TNF α activates the endothelium to upregulate the expression of the adhesion molecules E- and P-selectin, ICAM-1, PECAM-1, and VCAM-1. It potently stimulates these cells and macrophages to secrete chemokines (IL-8, MIP-1 α , and Gro- α) that enhance the affinity of leukocyte integrins for their ligands and induce leukocyte chemotaxis and recruitment.¹⁰⁵ TNF α also can induce HMGB1 release by activated macrophages, which generates a forward feedback mechanism, as HMGB1, by signaling through RAGE (see below), also induces TNF α release.^{106,107} TNF α by stimulating the release of tissue factor, PAF, von Willebrand factor, and thromboplastin generates a state of hypercoagulability. By inhibiting tissue-type plasminogen activator and thrombomodulin, it suppresses fibrinolysis, decreases protein C and S activation, and increases thrombin formation. However, TNF α also induces the release of a variety of anticoagulants (prostacyclin), fibrinolytics (urokinase-type plasminogen activator), and vasodilators (NO, PGE₂), which may offset or balance the tendency toward procoagulation. Most likely, the ultimate effect of TNF α depends on the location and quantity in which it is produced and the vascular bed with which it interacts.^{4,95}

3 Though clearly vital for host defense and microbial elimination, in severe infections, exuberant production and aberrant release of TNF α wherein it possess endocrine function and can cause a plethora of pathological sequelae. These systemic effects include fever by stimulating the production of PGE₂ by the hypothalamus (hence the name endogenous pyrogen), acute-phase protein production by the liver, cachexia, inhibition of myocardial contractility and vascular tonus, and intravascular thrombosis due to loss of normal anticoagulant properties of the endothelium and the production of tissue factor. TNF α is central to the pathogenesis of systemic inflammatory response syndrome (SIRS) and septic shock, and either state can be reproduced by the exogenous administration of TNF α .^{108,109} The organ dysfunction characteristic of these states may result from the hypercoagulability and subsequent tissue ischemia induced by this cytokine. Antagonists of TNF α can prevent mortality in experimental models, but clinical trials with anti-TNF α antibodies or with soluble TNF α receptors have been to no avail.^{4,108} That being said, anti-TNF α therapy has been pivotal in treating the more chronic diseases of rheumatoid arthritis, psoriasis, and Crohn's disease.

Soluble TNF receptors formed by proteolytic processing of both types of receptors bind and neutralize TNF α and serve as an endogenous regulator of cytokine activity.³⁹ TNF α also directly induces the

expression and release of TNF α inhibitors, including IL-10, corticosteroids, and prostanoids, which in a negative feedback loop suppress TNF α production and processing.⁹⁵ Hence, TNF α serves as its own regulator.

Interleukin-1

IL-1 possesses similar functions to TNF α in mediating a proinflammatory host response to insult; it is frequently released concomitantly with TNF α (Table 7-6).¹¹⁰ The major source of IL-1 is the mononuclear phagocyte. Synthesis and release are induced by LPS, cytokines such (TNF α , IL-2, TGF- β , all the interferons), antigen–antibody complexes, C5, and hypoxia.⁹⁵ IL-1 is also produced by neutrophils, B cells, helper T cells, epithelial cells, fibroblast, renal mesangial cells, and endothelial cells. There are two forms of IL-1; IL-1 α and IL-1 β . Both forms are active, bind to the same receptors and mediate the same effects. Most IL-1 found in circulation is IL-1 β .⁴

The two IL-1 receptors (IL-1R) are members of the Ig superfamily. IL-1RI is universally expressed and transduces the majority of IL-1 responses.^{111,112} IL-1RII expression is restricted to B cells, but may be induced on other cells. There is little evidence that this latter receptor serves any function, and in fact, may serve as a decoy.¹¹³ The cytoplasmic portion of IL-1RI is homologous to a domain of TLR, which mediate the cellular responses to endotoxin (Fig. 7-7). Engagement of IL-1 with IL-1RI induces the activation of the IL-1 receptor-associated kinase (IRAK) and the subsequent induction of the transcription factors NF κ B and AP-1.^{4,112}

Figure 7-7. Toll-like receptor (TLR) signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

The functions of IL-1 mirror those of TNF α , and synergy between the two cytokines is evident.¹¹⁰ IL-1 activates endothelial cells to increase cell surface expression of adhesion molecules and the production of prostaglandins, PAF, and a variety of CSFs. In doing so, it facilitates the recruitment and activation of appropriate leukocyte populations for specific localized immune responses. IL-1 also induces a procoagulant state by suppressing fibrinolysis through enhanced plasminogen activator inhibitor-1 and decreased tissue-type plasminogen activator activity. It increases thrombosis by stimulating tissue factor–like procoagulant and thromboplastin production and suppressing thrombomodulin release. It induces the synthesis of PAF, a potent vasoconstrictor and stimulus for platelet and leukocyte activation. However, similar to TNF α , it also stimulates the production of prostacyclin and urokinase-type

plasminogen activator, which promotes an antithrombotic state.¹¹⁴ At larger concentrations, its effects become systemic causing fever, the synthesis of acute-phase proteins, cachexia, myalgia, somnolence, and hypotension. It stimulates arachidonic acid and prostaglandin metabolism, and the release of pituitary stress hormones. It stimulates collagenase release and is a potent mitogen for neutrophils. Though similar in effect to TNF α , probably by activating similar signaling cascades and transcription factors, IL-1 does not induce apoptosis. Even at high concentrations IL-1 does not cause the physiologic derangements of septic shock.^{39,110}

Mononuclear cells produce the natural inhibitor of IL-1, IL-1ra. This IL-1 structural homologue is an inactive competitive inhibitor and may function as an endogenous regulator of IL-1. As with TNF α , attempts to inhibit IL-1 have not been of clinical benefit in human trials of sepsis.³⁹

Chemokines

This is a large family of cytokines that primarily govern leukocyte chemotaxis, hence the name^{115–119} (Table 7-6). Those bound on the endothelial surface induce leukocyte integrins to express a high-affinity state for their ligands, which is critical for tight leukocyte adherence and subsequent migration into the extravascular space. However, they also assist in orchestrating the migration of immune cells into lymphoid organs. Unlike other chemoattractants, members of this family possess a degree of specificity, influencing the recruitment of discrete subsets of leukocytes. They mediate their effects both directly and indirectly through the induction of other mediators such as histamine and ROS. Though some chemokines, in particular those regulating cell traffic through tissues, are constitutively produced (MIP-3 β and RANTES), most necessitate cellular stimulation for synthesis and release, in particular, those involved in inflammatory reactions. They are typically produced by macrophages, leukocytes, endothelial cells, fibroblasts, and many other cell types stimulated by LPS, phagocytosis, and inflammatory cytokines such as IL-1, TNF α , IL-6, and IFN γ .³⁹

Chemokines can be classified into four families based on the number and location of N-terminal cysteine residues. The two major families are the CC chemokines, in which the cysteine residues are adjacent, and the CXC chemokines, in which one amino acid is interposed between these cysteine residues. This amino acid sequence appears to account for the disparate influence, either promotion or inhibition, on neutrophil chemotaxis. The three amino acids that immediately precede the first cysteine are critical in defining receptor binding and neutrophil activation.^{120,121} This area has been designated the ELR motif. The other two chemokine families are represented by lymphotactin (C chemokine) and fractalkine (CX3C chemokine).³⁹

Chemokine receptors are seven transmembrane receptors that signal by G proteins and the formation of the second messengers, IP₃ and DAG (Fig. 7-5). Currently 6 CXC chemokine receptors, 11 CC, and 1 receptor each for the last two subfamilies have been identified and defined. The pattern of cellular expression of the receptors determines the specificity of the cellular response to binding.^{4,121}

CXC chemokines primarily govern the chemoattraction and activation of neutrophils, and to a lesser degree lymphocytes, in particular T cells. At least 12 different chemokines have been identified. They are clustered on chromosome 4 and demonstrate 20% to 50% homology at the amino acid level. IL-8 is the prototypical CXC chemokine.⁹⁸ It is produced by an array of immune and nonimmune cells including monocytes, alveolar macrophages, neutrophils, keratinocytes, mesangial cells, epithelial cells, fibroblasts, and endothelial cells. TNF α and IL-1 are key molecules for inducing IL-8. It is chemotactic for all granulocytes and influences nearly every aspect of neutrophil function. It stimulates neutrophil degranulation, phagocytosis, transendothelial migration and shedding of L-selectin, upregulation of β_2 integrins, and augments superoxide production. It is also a potent angiogenic factor. It binds to both the CXCR1 and CXCR2, receptors that also engage the chemokines GCP-2, GRO- α , and ENA-78. ENA-78 is a potent neutrophil chemotaxin produced by the endothelium in response to TNF α or IL-1, neutrophils, or monocytes. Studies have demonstrated that ELR-containing CXC chemokines are angiogenic, whereas those lacking this motif are angiostatic.^{39,95,120–122}

The interferon-influenced chemokines, IP-10 and Mig do not target neutrophils, and the ELR motif is absent. They induce IFN γ production and may play a more prominent role in mediating the inflammatory response to viral infections and autoimmune disorders. Mig is chemotactic for tumor infiltrating lymphocytes, activated T cells, and monocytes and promotes CTL activity. IP-10 is chemotactic for monocytes, T cells, and NK cells and augments T-cell adhesion. Both chemokines bind the CXCR3 receptor found on IL-2-activated T cells. IFN γ attenuates the expression of both IL-8 and ENA-78, and hence may serve as an important mechanism to the control and regulate inflammation.^{39,95} Stromal cell-derived factor-1 (SDF-1) is the only known ligand for the CXCR4 receptor and in the

presence of IL-7 stimulates proliferation of pre-B-cell clones and growth of bone marrow B progenitor cells. The receptor has gained much interest since it was identified as a coreceptor for HIV-1. PF4 and neutrophil-activating protein-2 are CXC chemokines of platelet origin. PL-4 has angiostatic properties and inhibits the growth of various cancer cell lines in a manner that appears to be related to its angiostatic properties. It binds heparin with high affinity to stimulate coagulation.³⁹

The CC chemokines recruit monocytes, granulocytes, T cells, NK cells and DCs. RANTES is produced by stimulated T cells, platelets, and endothelial cells and is constitutively produced in resting T cells, which implies a homeostatic function. MIP-1 α and β are produced by activated T cells and are chemotactic for neutrophils, monocytes, eosinophils, basophils, and T lymphocytes. They are also mitogenic for hematopoietic progenitor cells and upregulate TNF α , IL-1, and IL-6. The MCP family of chemokines influences the recruitment of monocytes and T cells. Their influence upon the function of these target cells is dictated by the cell's specific profile of receptor expression. MCP-1 is produced by nonlymphocytic cells (endothelial cells, epithelial cells, fibroblasts, smooth muscle cells, macrophages and mast cells). Binding to CCR1 enhances chemotaxis, whereas activation of CCR2 increases the release of intracellular substances such as histamine and LTs from basophils.³⁹

Lymphotactin is the only member of the C chemokine family and is produced by CD8⁺ lymphocytes, thymocytes, and NK cells, and, to a lesser degree, by DC and activated mast cells. It selectively recruits lymphoid cells.³⁹

Fractalkine is the sole CX3C chemokine and is produced by the endothelium. In its membrane-bound form it may act as a solid-phase adhesion molecule, but upon cleavage serves as a soluble chemoattractant for lymphoid cells and monocytes.³⁹

Interleukin-12 (NK Cell Stimulatory Factor, Cytotoxic Lymphocyte Maturation Factor)

IL-12 is integral in the innate immune response (Table 7-6). It is produced early during innate immune reactions and is critical for initiating a sequence of responses involving macrophages, NK cells, and T lymphocytes that results in the eradication of intracellular microbes. It stimulates subsequent adaptive responses that confer further host protection against these pathogens. Hence, it is an important link between innate and adaptive immune responses. IL-12 is primarily derived from activated mononuclear phagocytes and DCs, and most importantly stimulates IFN γ from T cells and NK cells. There are two pathways leading to IL-12 production: a T-cell dependent and an independent pathway. During innate immunity, LPS, infection by intracellular bacteria, and viral infections may induce IL-12 production. In addition, interactions between CD40 ligand and CD40 on activated lymphocytes and APC, respectively, induce the release of APC IL-12.^{123,124} Thus, IL-12 is produced during the induction of and the effector phases of cell-mediated immune response when APCs present antigens to T cells.^{4,39}

The IL-12 receptor is a heterodimer composed of β 1 and β 2 subunits, the latter of which is involved in signaling, although both are required for engaging ligand. The receptor signals through the JAK/STAT pathway (Fig. 7-8).⁴ This signal transduction pathway is employed by numerous cytokines including interferons, IL-6, IL-12, IL-2, IL-7, IL-9, IL-4, and IL-10. A characteristic of this cytokine is the generation of a positive amplification loop, which heightens the inflammatory response. Expression of the IL-12 receptor is induced by IFN γ . Activated NK cells and T_H1 cells produce IFN γ that potentiates macrophage IL-12 production. IL-12 stimulates further production of IFN γ by NK cells and T lymphocytes, which continues to fuel the reaction in a positive feedback mechanism. Ultimately, IFN γ activates macrophages to kill and degrade phagocytosed microbes. IL-12 potentiates bacterial LPS-induced macrophage TNF α production. IL-12 antagonists reduce mortality in experimental models of LPS-induced septic shock; however, there is no evidence of their efficacy in human clinical trials.⁴

4 5 CD4⁺ helper T lymphocytes, under the influence of IL-12, differentiate into T_H1 cells, which subsequently activate phagocytes in cell-mediated immunity. It enhances the cytolytic functions of activated NK cells and CD8⁺ CTLs, and suppresses T_H2 cell differentiation and effector activity. The inhibition of T_H2 and IL-4 activity confers antiallergic properties to IL-12. IL-12 knockout mice demonstrate diminished IFN γ production and defective T_H1 cell development and cell-mediated immunity against intracellular organisms.^{4,39}

Figure 7-8. JAK/STAT signaling pathway. JAK (Janus Kinase) components are associated in an inactive form with the cytoplasmic portion of cytokine receptors. Cytokine binding leads to receptor aggregation. Adjacent JAK proteins become activated and phosphorylate each other and tyrosine residues. Through the Src homology domain, STAT proteins bind phosphotyrosine residues on the cytoplasmic portion of cytokine receptors. Bound STAT proteins are phosphorylated by bound JAK proteins and subsequently dissociate. Phosphorylated STAT proteins dimerize and then move to the nucleus where they induce transcription by binding to STAT binding regions within the promoter. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

Interleukin-6

IL-6 regulates the acute-phase response to inflammation, characterized by altered thermoregulation (i.e., fever), perturbation in nitrogen balance (i.e., cachexia and catabolism), and the generation of the acute-phase reactants of innate immunity by the liver (Tables 7-6 and 7-7).^{95,125} It functions in both innate and adaptive immunity to enable the host to recover. Despite in vitro data demonstrating that a variety of cells can produce IL-6, the most prominent in vivo sources of IL-6 are monocytes and macrophages stimulated with LPS or IL-1 or fibroblasts and endothelial cells stimulated with TNF α .¹²⁶ Steroids inhibit the induction of IL-6. The receptor for IL-6 consists of cytokine-binding protein and a signal-transducing subunit, which belong to the type I cytokine receptor family. It signals through the JAK-STAT pathway (Fig. 7-8).⁴

In conjunction with IL-1 and TNF α , IL-6 regulates the systemic manifestations of the acute-phase response.¹²⁵ It potentiates the immune response by inducing B-cell differentiation and activating T cells. It interacts with TNF α to enhance T-cell proliferation and promotes neutrophil activation and accumulation. In adaptive immunity, IL-6 stimulates the growth of B lymphocytes that have differentiated into antibody-producing plasma cells. IL-6 antagonizes LPS-induced TNF α production and TNF α -induced IL-1 production.^{127,128}

Table 7-7 Acute-Phase Proteins

Acute-Phase Protein	Function
Increase	
C-reactive protein	Opsonin
Serum amyloid A	Apolipoprotein
α_1 -Acid glycoprotein	Platelet inhibitor
Fibrinogen	Coagulation, tissue repair
α_2 -Macroglobulin	Antiprotease
α_1 -Protease inhibitor	Antiprotease
α_1 -Antichymotrypsin	Antiprotease
Haptoglobin	Antioxidant
Hemopexin	Antioxidant
Ceruloplasmin	Antioxidant
C3	Complement
Factor b	Complement
C1 inhibitor	Complement
C4b-binding protein	Complement
Mannose-binding lectin	Complement
Decrease	
Albumin	Transport
Prealbumin	Transport
Transferrin	Transport

High Mobility Group Box 1 Protein

HMGB1 was initially identified as an architectural chromatin-binding factor that bends DNA and directs protein assembly on specific DNA targets. It is abundant, ubiquitous, and evolutionarily conserved, as evident by the 99% amino acid homology between rat and human proteins.⁵⁶ Thirty years after its original discovery, Tracey et al. demonstrated that HMGB1 acts as a late mediator of mortality in murine endotoxemia and sepsis. HMGB1 appeared 8 hours poststimulation and plateaued at 16 to 32 hours, very distinct from the acute rise and fall of early mediators (TNF α , IL-1 β) of severe sepsis and septic shock.⁵⁶ Recent studies show that systemic concentrations are elevated in those patients who die of sepsis.¹²⁹

HMGB1 is the prototypical DAMP. When cells die by necrosis (i.e., nonprogrammed cell death), HMGB1 is released into the extracellular medium. In contrast, apoptotic cells modify their chromatin so that HMGB1 irreversibly binds, and thus is not released.^{130,131} However, HMGB1 may also be released by activated macrophages and NK cells, via an active process that necessitates shuttling the protein from nucleus to cytoplasm; this event does not require further synthesis.^{130–132} Acetylation of HMGB1 appears essential for release, however acetylation of histones as occurs during apoptosis, strengthens its interaction with chromatin and inhibits release.^{130,131} Interestingly, though apoptotic cells do not release HMGB1, macrophages engulfing apoptotic cells do. Recent studies have shown that nucleocytoplasmic shuttling of HMGB1 involves serine phosphorylation by CaMKIV that enables it to be translocated to the cytoplasm by 14-3-3 and CRM1 chaperones.^{133,134} Subsequent release of cytoplasmic HMGB1 appears to involve active secretion through a secretory lysosomal pathway.^{130,132}

HMGB1 has many of the intercellular signaling activities characteristic of cytokines and therefore is often classified as a proinflammatory cytokine and potent regulator of the inflammatory response. In light of the fact that it is released by macrophages responding to bacterial challenge or by injured cells, it may mediate inflammation consequent to sepsis or trauma. After release, signaling is thought to occur by binding to RAGE with subsequent activation of p21ras, MEK, the MAPK kinases, and NF κ B.^{106,135} This receptor is expressed on mononuclear phagocytes, vascular smooth muscle cells, and neurons. Blocking antibodies to RAGE fails to completely prevent cellular activation suggesting the presence of an alternate receptor. Recent studies suggest that both TLR2 and TLR4 may mediate HMGB1-induced activation of NF κ B in macrophages and neutrophils. This observation is very important as it demonstrates that a receptor classically considered specific for microbial danger signals, may interact with an endogenous molecule.^{56,106,135}

HMGB1-RAGE interactions induce numerous proinflammatory events. Endothelial cells increase the expression of adhesion molecules and secrete TNF α and IL-8.¹³⁶ In neutrophils, HMGB1 activates MAPKs and enhances the expression of proinflammatory cytokines in a NF κ B-dependent manner. In addition, it is chemotactic for neutrophils, monocytes, macrophages, and DCs.¹⁰⁶ Intratracheal administration of HMGB1 to LPS-resistant mice stimulated lung neutrophil accumulation and the local production of proinflammatory cytokines.¹⁰⁶ HMGB1 has potent immunostimulatory actions and

promotes the maturation of both myeloid and plasmacytoid DCs. Systemic levels are markedly elevated in patients who die of sepsis, and animal studies suggest that this association is causal.¹²⁹ Recombinant HMGB1 mimics the lethality of high-dose LPS and induces the release of TNF α by macrophages. However, intravenous administration of HMGB1 does not cause shock like TNF α . More recent data call into question whether HMGB1 itself can directly promote the secretion of proinflammatory cytokines (TNF α , IL-1 α/β , IL-6, IL-8) and chemokines (MIP1 α/β) as initially reported. A direct proinflammatory activity of HMGB1 has not been reproduced consistently, raising some concern that this might be based on the formation of specific complexes with other molecules such as LPS. Recent studies show that highly purified recombinant HMGB1 has very weak direct proinflammatory activity.¹³⁷

In a series of elegant studies, anti-HMGB1 antibodies conferred a dose-dependent protection in animal models of endotoxemia, even when the first dose of anti-HMGB1 antibodies was delayed for 2 hours.⁵⁷ This occurred without changes in TNF α , IL-1 β , or MIP-2 concentrations. Even more striking are the *in vivo* CLP models, in which anti-HMGB1 administration up to 24 hours after CLP significantly increased survival, 72% versus 28%.⁵⁷ This wider therapeutic window may enable the development of inhibitors of HMGB1 for treatment of sepsis.^{106,138–140} These observations have stimulated the search for other inhibitors of HMGB1. Ethyl pyruvate a nontoxic food additive, dose dependently inhibits HMGB1 release, and confers significant protection against the lethality of sepsis, even when the first dose is administered 24 hours after the onset of sepsis. In addition, it inhibits the translocation of NF κ B and p38 MAPK signaling.^{106,138,141,142}

HMGB1 may also serve as a danger signal for other perturbations in homeostasis, as it can also be released passively by necrotic or injured cells but not apoptotic cells.^{131,140,143,144} Hypoacetylation of chromatin on the induction of apoptosis enhances HMGB1 binding, thereby preventing release during apoptotic processes. Thus, HMGB1 binding to chromatin depends on the viability of the cell and clearly distinguishes necrotic from apoptotic cells. This enables the innate immune response to respond to injury and further induce inflammation.^{131,140,143,144}

HMGB1 is also elevated during hemorrhage shock.¹⁴⁵ In a clinical case, serum HMGB1 levels increased significantly within 24 hours of hemorrhagic shock and returned toward basal levels as the clinical condition improved.¹⁴⁶ HMGB1 also appears to mediate cell damage and death in other noninfectious insults. In a model of warm liver ischemia reperfusion, HMGB1 inhibition attenuates hepatocellular injury.³² Interestingly, this protection, as well as reduced systemic concentrations of HMGB1, was also afforded by inhibiting CaMK.³²

High levels of HMGB1 have also been found in other conditions of sterile inflammation such as rheumatoid arthritis.^{147–149} In human arthritis, overexpression of HMGB1 at the site of joint inflammation may be detected in the synovial fluid of rheumatoid arthritis patients.^{148,149} HMGB1 may in fact amplify the effect of local cytokines as suggested by its ability to stimulate macrophages derived from synovial fluid of rheumatoid arthritis patients to release TNF α , IL-1 β , and IL-6.^{147,150} Hence, HMGB1 may serve as a signal of danger from endogenous threats or perturbations.

Interleukin-15

IL-15 is produced by various cells in response to LPS and other stimuli, though the principal cellular source is mononuclear phagocytes. (Table 7-6). It is structurally homologous to IL-2, as is its receptor and the IL-2R. IL-15 stimulates the proliferation of NK cells similar to the manner by which IL-2 functions later in the adaptive immune response. It also acts as a T-cell growth and survival factor especially for long-lived memory CD8⁺ T cells.⁴

Interleukin-18

IL-18 is structurally homologous to IL-1 and utilizes a similar IRAK signaling pathway (Table 7-6). Macrophages responding to microbial challenge or exposure to LPS are the principal source. Its primary function is to stimulate the production of IFN γ by NK cells and T cells, and in synergizing with IL-12, augments cell-mediated immunity. Knockout mice lacking IL-18 are deficient in IFN γ production, and concomitant IL-12 deficiency eliminates all IFN γ production and any T_H1 response.⁴

Interferons (Type I)

Type I interferons possess potent antiviral and antitumor properties (Table 7-6). It is from this ability to “interfere” with viral infection that the name is derived. They are subcategorized into α and β interferons. Mononuclear phagocytes are the major source of interferon α , whereas many cell types produce interferon β . The most potent stimulus inducing the synthesis and release of either is viral infection, particularly double-stranded RNA produced during viral replication. Other inducers include IL-

1, $\text{TNF}\alpha$, LPS, and antigen-activated T cells. Both groups bind to the same cell surface receptor and induce similar responses by signaling through the JAK/STAT pathway (Fig. 7-8).

These cytokines provide the first line of defense against viral infection and promote cell-mediated immunity against intracellular pathogen. They are secreted from virally infected cells to protect neighboring uninfected ones by inducing the synthesis of a number of enzymes that interfere with viral RNA or DNA transcription and viral replication. Through enhanced expression of class I MHC molecules, the type 1 interferons facilitate recognition of class I-associated viral antigens on infected cells by CTLs and increase the efficiency of CTL-mediated killing. Type I interferon stimulates the development of $\text{T}_\text{H}1$ cells by promoting these cells to express IL-12 receptor. They can also stimulate B-cell development, proliferation, and immunoglobulin heavy chain switching from IgM to IgG.^{151–153} Knockout mice lacking the receptor for these cytokines are susceptible to viral infections. Interferons are currently in clinical use for hepatitis B and C infection, multiple sclerosis, CML, and Kaposi's sarcoma.^{151–153}

Interleukin-10 (Cytokine Synthesis Inhibiting Factor)

IL-10 inhibits activated macrophages and APC and functions in a counterregulatory mechanism to suppress innate immune reactions (Table 7-6). It is produced mainly by macrophages, and hence functions by negative feedback. T lymphocytes, particularly the $\text{T}_\text{H}2$ subset, B cells, and some other nonlymphoid cells produce IL-10, in response to a variety of stimuli including LPS, $\text{TNF}\alpha$, IL-2, IL-4, and IL-13.

IL-10 binds to a type II (interferon) receptor. Though the manner by which it effects curtailment of the inflammatory response is unknown, its presence inhibits $\text{N}\kappa\text{B}$ activation and the generation of inflammatory mediators. Thus, it may inhibit, in some manner, the activation of signal transduction cascades and gene activation in proinflammatory pathways.^{4,154}

IL-10 terminates many of the functions of activated macrophages and participates in reestablishing homeostasis as the infection resolves. It downregulates proinflammatory cytokine ($\text{TNF}\alpha$, IL-1, IL-6, and IL-8) production, suppresses the production of IL-12, and inhibits $\text{IFN}\gamma$ production and the innate and cell-mediated immune responses.^{4,59,95} It represses the expression of costimulators and class II MHC molecules on APC, thereby terminating T-cell activation and inhibiting cell-mediated immunity.⁴ In neutrophils it inhibits cytokine release, superoxide generation, migration, and even survival.¹⁵⁵ In combination with IL-4 it inhibits $\text{IFN}\gamma$ release and IL-12 production to limit differentiation and function of $\text{T}_\text{H}1$ cells, favoring a $\text{T}_\text{H}2$ profile.⁵⁹

IL-10 knockout mice develop inflammatory bowel disease, which is hypothesized to result from unregulated macrophage reaction to enteric microbes.¹⁵⁶ In observational studies of ARDS or MODS, serum IL-10 levels were often elevated, and those patients with the highest systemic concentrations died.¹⁵⁴ It is unclear whether this is actually a pathologic response, or merely a marker of disease severity. Contemporary belief is that IL-10 is not a mediator of immunosuppression, but rather, important for immunoregulation.

Late Cytokines/Adaptive Immunity

Interleukin-2 (T-Cell Growth Factor)

IL-2 stimulates the growth and proliferation of T lymphocytes and is responsible for T-cell clonal expansion after antigen recognition (Table 7-6).¹⁵⁷ IL-2 is produced by CD4^+ , and to a lesser extent CD8^+ T cells. The receptor is heterotrimeric, consisting of three noncovalently associated proteins α , β , and γ . The α and β chains are involved in cytokine binding, and the β and γ chains mediate signal transduction.⁴ Antigen recognition enhances the expression of functional IL-2 receptors, which confers a degree of specificity, as those T cells recognizing antigen are preferentially induced to proliferate in response to IL-2. Though, the α chain appears on T cell activation and binds IL-2, signal generation necessitates the β and γ chains. Cells expressing the complete α , β , and γ complex bind IL-2 with higher affinity (kD of 10^{-11} M), and growth stimulation of such cells occurs at a low IL-2 concentration.⁴ Upon antigen receptor-mediated T-cell activation, IL-2R α is rapidly upregulated, which reduces the concentration of IL-2 needed to stimulate growth. Therefore, antigen-stimulated T cells are more responsive to IL-2 than naïve T cells. This receptor signals through numerous signal transduction pathways including the JAK/STAT and MAP kinase pathways (Figs. 7-5 and 7-8).

IL-2 functions in an autocrine and paracrine fashion to induce the proliferation of the antigen-specific cells. After exposure to IL-1, there is a rise in cyclins and activation of cyclin-dependent kinases that stimulates the progression of the cell cycle from the G1 to the S phase. A reduction in p27, an inhibitor of cyclin-kinase complexes, facilitates this progression, and the induction of Bcl-2, an antiapoptotic

protein, facilitates survival. It also stimulates the production of other cytokines such as IFN γ and IL-4.⁴

IL-2 promotes the proliferation and differentiation of many immune cells. NK cells are stimulated to grow and transform into lymphocyte-activated killer cells. In combination with IFN γ and IL-12, IL-2 can trigger a positive feedback cycle of NK activation. IL-2 stimulates B-cell growth and antibody synthesis. Repeated activation of CD4⁺ T cells in the presence of IL-2 sensitizes these cells to apoptosis by fas-fas-ligand. IL-2 may also stimulate the development of regulatory T cells, and IL-2 knockout mice develop autoimmunity. Knockout mice lacking the γ chain develop X-linked severe combined immunodeficiency syndrome. This is probably due to an inability of immature T cells to respond to IL-7. IL-2 has been used in the management of cancer, in particular renal cell carcinoma.¹⁵⁸

Interleukin-4

IL-4 is the major stimulus for the production of IgE antibodies and for the development of T_H2 cells from naïve CD4⁺ T cells (Table 7-6). The principle cellular sources are CD4⁺ T cells, mast cells, and basophils. The IL-4 receptor belongs to the type I cytokine receptor family and signals through the JAK/STAT pathway.¹⁵⁹ (Fig. 7-8). IgE is integral in orchestrating the defense against parasitic infections. It stimulates IgE production and mast cell/eosinophil-mediated reactions, and induces B cell Ig heavy chain class switching to the IgE isotype. However, IL-4 also serves a counterregulatory role by inducing T_H2 cell differentiation and growth. IL-4 antagonizes the macrophage-activating effects of IFN γ and thus inhibits cell-mediated immunity.

Interleukin-5

IL-5 is produced by T_H2 cells and activated mast cells and activates eosinophils, (Table 7-6). It signals through the type I cytokine receptor and the JAK/STAT pathway (Fig. 7-8). IL-5 is an inducer of eosinophil growth, differentiation, and activation, and also participates in the eradication of helminthic infection. IL-5 also stimulates the proliferation of B cells and the production of IgA antibodies.⁴

Interleukin-13

IL-13 is produced by T_H2 cells and some epithelial cells and is structurally homologous and functionally similar to IL-4 (Table 7-6). The receptor is found mainly on nonlymphoid cells and can be activated by either IL-13 or IL-4. IL-13 downregulates the expression of Fc γ on monocytes and macrophages, thereby decreasing antibody-dependent cellular cytotoxicity. It increases 15S-HETE and lipoxin A₄, both of which antagonize proinflammatory LTs. However, they can increase the expression of MHC class II and costimulatory molecules on monocytes, and thereby serve an immunostimulatory function. The major action is to inhibit the activation of macrophages and to antagonize IFN γ .¹⁶⁰

Interferon γ

IFN γ is produced by NK cells, T_H1 cells, and CD8⁺ cells, and as the principal stimulus for macrophage activation, provides necessary functions during both innate and adaptive immune responses (Table 7-6). It modulates cellular differentiation, cytotoxicity, cytokine production, cellular adhesion, and oxidative metabolism. During innate immunity, NK cells secrete IFN γ upon exposure to pathogen or stimulation by IL-12. CD8⁺ T cells and the T_H1 subset of CD4⁺ T cells produce it in response to MHC-bound peptide antigen with a costimulatory signal. The IFN γ receptor is composed of two homologous proteins belonging to the type II cytokine receptor family and functions through the JAK/STAT pathway (Fig. 7-8).⁴

The antiviral and antitumor properties of IFN γ are redundant with those of type I interferons. In concert with TNF α and IL-12 it forms one arm of a positive feedback loop fueling the activation of both NK cells and macrophages. Stimulated macrophages activate NK cells by releasing TNF α and IL-12. These NK cells produce IFN γ , which further stimulates macrophages to secrete more TNF α and IL-12.^{161,162}

IFN γ induces the genes encoding the enzymatic machinery required for generating ROS generation and provides the principle stimulus for macrophages to kill phagocytosed microbes. It regulates the expression of MHC class I and class II molecules and costimulators of APC, and induces the transcription of enzymes regulating antigen processing.^{161,162}

IFN γ synergizes with TNF α to activate the endothelium and upregulate adhesion molecule expression; in doing so it facilitates lymphocyte recruitment and leukocyte recruitment. Interferon promotes the differentiation of naïve CD4⁺ cells into T_H1 cells and inhibits the proliferation of T_H2 cells, in part, by inducing IL-12, the major T_H1-inducing cytokine, from activated mononuclear phagocytes. It promotes

B-cell switching to certain IgG subclasses, notably IgG2a, and inhibits the switching to IL-4–dependent isotypes such as IgE and IgG1. These IgG subclasses bind the Fc γ receptors on phagocytes and activate complement, thereby promoting phagocytosis of opsonized microbes. It activates PMNs and stimulates the cytolytic activity of NK cells. The net effect is to promote macrophage-rich inflammatory reactions while inhibiting IgE-dependent eosinophil-rich reactions. IL-10, by suppressing macrophage release of TNF α and IL-12, negatively regulates IFN γ production.

IFN γ also demonstrates counterregulatory properties. It selectively inhibits LPS-induced expression of CXC chemokines. It upregulates macrophage production of IP-10, MIG, and ELR-negative chemokines that inhibit neutrophil chemotaxis and activation and decreases macrophage release of ELR-positive CXC chemokines (e.g., IL-8), which are chemotactic for neutrophils.⁴

Transforming Growth Factor β

Transforming growth factor β (TGF β) is a homodimer synthesized and secreted by activated T cells, macrophages, and many other cells (Table 7-6). It is primarily immunosuppressive and inhibits the proliferation and activation of lymphocytes and other leukocytes. It promotes wound healing by increasing extracellular matrix protein synthesis and stimulating mononuclear cell and fibroblast influx.^{163–165} Though the family consists of three closely related isoforms, most cells utilize TGF β . Its effects are mediated through two high-affinity TGF receptors (type I and II) that signal through a serine/threonine kinase domain that phosphorylates transcription factors called SMADS.⁴

TGF β inhibits the proliferation and differentiation of T cells and the activation of macrophages. It favors differentiation of CD4⁺ cells to the T_H2 subset, and inhibits MHC class II surface expression. By suppressing the expression of MHC class II antigen, it abrogates the adaptive immune response. Macrophages demonstrate diminished ROS production and TNF α and NO release. It directly counteracts the influence of proinflammatory cytokines on PMNs and endothelial cells, and in combination with IL-4, IL-13, and IL-10 can antagonize the production or effects of these proinflammatory mediators. Knockout mice, deficient in TGF β develop uncontrolled inflammatory lesions.^{4,39}

Cytokines that Stimulate Hematopoiesis

Cytokines are necessary for normal hematopoiesis. Several of the cytokines stimulated during both innate and adaptive immune responses are mitogenic for and induce differentiation of bone marrow progenitor cells. CSFs are cytokines made by activated T cells, macrophages, endothelial cells, and bone marrow stromal cells that stimulate increased production of inflammatory leukocytes by bone marrow progenitors. Receptors for GM-CSF and G-CSF are of the class I family of cytokine receptors. GM-CSF is expressed by T and B cells, macrophages, mast cells, fibroblasts, and endothelium in response to stimuli such as IL-1, IL-2, LPS, and TNF α . It stimulates neutrophils, monocytes, macrophages, and DC and is a powerful inducer of hematopoiesis. It enhances cytokine release, degranulation, and phagocytosis of opsonized particles in neutrophils. In monocytes and macrophages it enhances cytotoxicity and cytokine release. It promotes the activity of APCs and the maturation of bone marrow cells into DCs and monocytes.¹⁶⁶ G-CSF is produced by macrophages, endothelial cells, fibroblasts, and bone marrow stromal cells. It functions as an endocrine hormone to mobilize neutrophils and induces subsequent leukocyte proliferation and maturation. In 1991, the FDA approved the use of G-CSF for use in patients with neutropenia.^{167,168}

Stem cell factor or c-Kit ligand is synthesized by marrow stromal cells and binds to a cell surface tyrosine kinase receptor on pluripotent stem cells that is the protein product of the cellular proto-oncogene c-kit. Its effects appear to be permissive, as it is corequisite for stem cell responsiveness to other CSFs, yet in isolation does not stimulate colony formation. It may also play a role in sustaining the viability and proliferative capacity of immature T cells in the thymus.⁴

IL-3 is a product of CD4⁺ T cells that promotes the differentiation of immature marrow progenitors into all known mature cell types. It also promotes the growth and development of mast cells. Surprisingly, despite these important functions, murine knockouts do not manifest noticeable impairment of hematopoiesis.⁴

IL-7 is secreted by bone marrow stromal cells and promotes the growth and survival of immature precursors committed to the B and T lymphocyte lineages. Knockout mice, deficient in IL-7 or its receptor, are lymphopenic and possess diminished populations of B and T cells.⁴

The Complement System

6 The complement system is integral to both innate and adaptive immunity. It has the capacity to

independently eliminate organisms and to facilitate host defense by marking foreign particles for phagocytosis through opsonization. Many pathophysiologic inflammatory diseases, immune complex diseases, ischemia/reperfusion injury, and ARDS are considered consequences of excessive or unregulated induction of this system.¹⁶⁹⁻¹⁷²

The system consists of three pathways comprised of approximately 30 serum and cell surface proteins that interact with one another and with other molecules of the immune system in a highly coordinated fashion. These cascades involve the sequential proteolytic activation of zymogens to generate enzymes with proteolytic activity. This mechanism for activation amplifies the response because each individual enzyme activated can cleave numerous zymogens in the next step and generate multiple activated enzyme molecules. Ultimately, the products of complement activation adhere to microbial cell surfaces or to antibody-bound microbes and other antigens to directly or indirectly eliminate these pathogens. Temporal and spatial regulation to the focus of infection is ensured both by the transience of activation of these enzymes in the absence of microbes or antigens and by several circulating proteins that provide surveillance.^{169,171}

The complement cascade is divided into three distinct pathways: (1) the classical pathway (humoral immunity), which is activated by antibody bound to antigen, (2) the alternative pathway (innate immunity) in which complement is activated by components of microbial cell surfaces, and (3) the mannose/lectin pathway (innate immunity), which is activated by a plasma lectin that binds to mannose residues on microbes. Despite differences in which the cascade is activated, all three complement pathways ultimately result in the cleavage of C3 and share the same late cascade.^{169,171}

The alternative pathway functions in the absence of antibody and is phylogenetically the oldest pathway (Fig. 7-9). Bacteria, viruses, fungi, and parasites all function as stimuli. Initial activation begins with the cleavage of C3 and the stable attachment of its product C3b to the microbial surface. Bound C3b finds factor B, which is subsequently cleaved by a plasma serine protease called factor D to generate Bb. The C3bBb complex is called the alternative pathway C3 convertase and functions to cleave more C3. In doing so the convertase serves as an amplification step in both the classical and alternative pathways. Properdin prolongs the half-life of C3 convertase by delaying the release of Bb from C3bBb. C3b is the recognition component of the alternate pathway and is responsible for the opsonization of bacteria. C3a in conjunction with C5a and C4a induces acute inflammation by activating mast cells and neutrophils. These inflammatory mediators play a significant role in increasing blood vessel permeability, vasodilatation, edema formation, neutrophil adhesion and activation, chemotaxis, and the release of toxic oxygen species and lysosomal enzymes from phagocytic cells. The binding of another C3b to this complex generates the alternative pathway C5 convertase, C3bBb3b.^{4,169,171}

Figure 7-9. Complement pathways. Alternate Pathway: 1. C3 is cleaved to C3b. 2. C3b binds and cleaves B to Bb to form C3 convertase (C3bBb). 3. Another C3b binds C3 convertase to form C5 convertase (C3bBbC3b). Classical Pathway: 1. C1 binds immunoglobulin. 2. C1 binds and cleaves C4 and C2 to C4b and C2a to form C3 convertase (C4b2a). 3. C4b2a binds another C3b to generate C5 convertase (C4b2aC3b). Late Pathway: 1. C5 convertase cleaves C5 to form C5b, which integrates into the plasmalemma. 2. C6–8 are recruited, forming the C5b-8 complex. 3. C5b-8 recruits numerous C9 subunits, which form a pore in the pathogen cell wall. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. 5th ed. Philadelphia, PA: Saunders; 2003.)

Activation of the alternative pathway is restricted to the cell surface of microbes, as mammalian cells possess several regulatory proteins to rapidly degrade any C3bBb. Excessive amplification is regulated by factor H and factor I. H accelerates the decay and delays the formation of C3bBb. It also acts as a cofactor for I to degrade C3 into iC3b, which is unable to bind B to generate C3 convertase. Decay acceleration factor hinders C3 convertase assembly and mediates its dissociation in all three pathways. Also, the protein properdin, which stabilizes this alternative pathway C3 convertase, has a higher affinity for microbial than mammalian cell surfaces.^{4,169,171}

The classical pathway is the primary mediator of adaptive humoral immunity and is initiated by binding of the complement protein C1 to IgG or IgM molecules engaged with antigen (Fig. 7-9). Other substances such as lipid A in endotoxin and mitochondrial membranes may activate this pathway independent of antigen-antibody complexes in vitro.^{169,173}

C1 is a calcium-dependent trimeric protein consisting of C1q, which recognizes and binds the Fc region of the immunoglobulin, and C1r and C1s, which are proteases. C1q engages the Fc portion of the immunoglobulin μ and γ heavy chains. Each Fc region has a single C1q binding site, yet for activation, each C1q molecule must bind to two Ig heavy chains. Hence, multiple antibodies must be approximated for activation, which restricts activation to foci of immunoglobulin engagement. IgM exists as a pentamer enabling it to bind to two C1q molecules, and hence it is more efficient at complement activation.^{4,169,173}

Interaction between C1q and the immunoglobulin Fc region induces a conformational change in C1q that activates C1r, which subsequently cleaves and activates C1s. C1s cleaves C4 to generate C4b and C4a. The C4a anaphylatoxin possesses properties similar to those described for C3a. C4b localizes to immune complexes on the cell surface. C2, after complexing with C4b, is cleaved by C1s, thereby generating the classical C3 convertase C4b2a complex, which has the ability to cleave C3. The C3b generated can bind Bb, producing more C3 convertase and amplifying the signal. The key early steps of the alternative and classical pathways are analogous: C3 and factor B of the alternative pathway are homologous to C4 and C2 in the classical pathway. C3b can also combine with the classical C3 convertase to generate C4b2a3b, the classical C5 convertase.⁴

Numerous regulatory mechanisms exist to restrict activation to sites of inflammation. Excessive classical C3 convertase activity is prevented by the rapid decay of C2a from the complex, which renders the complex unstable. C1 inhibitor covalently binds C1s, reducing the half-life of activated C1 to only 13 seconds. C4-binding protein enhances spontaneous dissociation of C4b2a and also acts as a cofactor for C3b/C4b inactivator, which degrades C4b.³⁹

The mannose-binding lectin (MBL) pathway is activated by microbial polysaccharides bound to circulating lectins; MBL serves as the recognition unit of the MBL pathway. This pathway recognizes polysaccharides with high mannose content and other oligosaccharides with characteristic linkages found exclusively on pathogens and not on normal host components. Binding is calcium dependent and results in the activation of mannose-binding lectin-associated serine proteases (MASP-1 and MASP-2). Activated MASP-2 cleaves and activates C4 and C2 in the same fashion as the classical complement pathway. Subsequent steps of complement activation of the MBL pathway mirror those of the classical complement pathway.^{169,174,175}

The C5 convertases generated during either the classical or alternative pathway initiate a cascade of events that culminates in the formation of the cytotoxic MAC. Specifically, C5 convertase cleaves C5, yielding C5a and C5b. C6 and C7 bind to generate the C5b67 complex. This hydrophobic moiety penetrates deeply into the lipid bilayer as a high-affinity receptor for C8. Binding of C8 forms the complex C5b-8 that recruits numerous C9 subunits, which polymerize to form pores in the plasma membrane of bacteria. The pores structurally resemble the membrane pores formed by perforin, the cytolytic granule protein found in CTLs and NK cells. Their diameter may span 100 Å, which prevents the maintenance of vital ionic gradients, induces osmotic lysis, and ultimately the death of target cells or pathogens. Patients with deficiencies in the terminal components of C5, C6, C7, and C8 are susceptible to meningococcal and gonococcal infections.^{4,176} By contrast, recent studies suggest that aberrant induction of the complement system, specifically C5a, plays an integral role in inducing paralysis of the innate immunity and the development of ARDS and MODS.

The effects of complement are in part mediated through several complement receptors. Opsonization and phagocytosis are important mechanisms for pathogen destruction, and phagocytic cells express receptors for complement factor C3 components. Complement receptor type 1 (CR1), the C3b receptor for C3b and C4b, mediates engagement of and facilitates phagocytosis of complement-bound microbes and the clearance of immune complexes from the circulation. It is expressed on a variety of cells

including RBC, neutrophils, monocytes, eosinophils, and T and B cells. RBCs facilitate elimination by transporting these opsonized particles to the liver and spleen where the immune complexes are removed by phagocytes. CR2 stimulates humoral immune response by enhancing B cell activation by antigen and by promoting the trapping of antigen–antibody complexes in germinal centers. In humans, this receptor is the receptor for EBV. CR3 and CR4 are β_2 integrins that bind the iC3b-processed fragment of C3 and promote macrophage and neutrophil phagocytosis of iC3b-opsonized antigen.^{4,39}

This entire cascade is under strict regulation to ensure that activation is restricted to sites of inflammation and infection. This regulation is needed as low-level activation is always occurring, and if not quelled, would certainly damage normal tissues. Even when locally activated, byproducts may damage nearby cells and tissues. Several circulating proteins function to do this. C1r and C1s are inhibited by C1 inhibitor, a serine protease inhibitor that mimics C1r and C1s. C1 inhibitor targets activated C1qrs, and after attachment, C1r-C1s dissociates and activation of classical complement ceases. This inhibition prevents the accumulation of active C1r-C1s, thereby limiting the duration during which active C1r-C1s can initiate the cascade.⁴ C1 inhibitor also inhibits other circulating inflammatory serine proteases including kallikrein and factor XII, both of which can activate the formation of bradykinin.⁴ Hereditary angioneurotic edema is an inherited deficiency of C1 inhibitor and manifests as acute intermittent edema of the skin and mucosa causing abdominal pain, vomiting, diarrhea, and airway obstruction.

MCP, type 1 complement receptor (CR1) and DAF are regulatory proteins that bind to C3b and C4b deposited on cell surfaces and competitively inhibit the binding of other components of the C3 and C5 convertases, such as Bb and C2a, and thereby block further progression of the cascade. These proteins are only produced by mammalian cells. Deficiency of an enzyme required to form the linkages necessary to express DAF underlies paroxysmal nocturnal hemoglobinuria, a disease characterized by recurrent intravascular hemolysis due to unregulated complement activation on the surface of erythrocytes. Cell-associated C3b is proteolytically degraded by a plasma serine protease called factor I which is active only in the presence of regulatory proteins such as MCP, factor H, C4BP and CR1. MAC formation is inhibited by CD59, a membrane protein that incorporates itself into growing MACs and inhibits the incorporation of C9. It is not present in microbes. The function of these regulatory proteins may be overcome by increasing amounts of complement activation.⁴

Lipid Mediators

Eicosanoids

7 Eicosanoids are 20-carbon lipid inflammatory mediators that are derived from membrane arachidonic acid and are involved in numerous homeostatic processes and inflammation. These lipid mediators are not stored in tissues, but are synthesized de novo within seconds in response to a variety of stimuli, including mechanical trauma, specific cytokines, growth factors, and other mediators (Fig. 7-10). Although most cells are capable of producing eicosanoids, neutrophils and macrophages are the predominant sources. They are rapidly degraded in the circulation, which limits their role primarily to that of autocrine and paracrine mediators of local inflammatory changes.^{177–179}

The liberation of the precursor molecule, arachidonic acid, is the major rate-limiting step. The family of PLA₂, in particular type IV cytosolic PLA₂, is responsible for eicosanoid production; cells lacking type IV PLA₂ are devoid of eicosanoid synthesis.¹⁸⁰ Many PLA₂ are transcriptionally regulated by IL-1 and TNF α , whereas others are regulated by the MAP kinase pathway and by calcium-dependent translocation to membranes. Once formed, arachidonic acid metabolism proceeds along one of the two pathways.^{177–179}

Cyclooxygenase Pathway (Prostaglandins)

Cyclooxygenase catalyzes the initial step of a series of reactions that converts arachidonic acid to prostanoids (Fig. 7-10). There are two isoforms, COX1 and COX2; the former is constitutively expressed, whereas COX2 is inducible. COX2 is considered more important during inflammatory processes such as fever, hyperalgesia, and edema formation. Either enzyme catalyzes the conversion of arachidonic acid to the endoperoxidase PGG₂, which is subsequently converted to PGH₂. PGH₂ serves as the precursor to numerous specific prostaglandins. All of these products possess very short half-lives and are rapidly inactivated.^{180,181}

Prostaglandins mediate their effects through G protein signaling (Table 7-8). Prostacyclin (PGI₂) is produced by the endothelium as a potent vasodilator and inhibitor of platelet aggregation and adhesion;

these characteristics enhance tissue perfusion. PGI₂ inhibits neutrophil chemotaxis and activation and interacts synergistically with PGE₂ to increase vascular permeability through the bradykinin pathway. PGE₂ is the predominant anti-inflammatory prostaglandin and is produced by nearly all inflammatory cells. It is produced in response to IL-1 and mediates the hypothalamic fever response and synergizes with bradykinin and histamine to mediate pain. It is a bronchodilator, inhibits both IL-1 production and T-cell responsiveness to IL-1, and at low concentrations suppresses TNF α production. It also inhibits neutrophil chemotaxis and activation and T_H1 lymphocyte proliferation.^{180,181} There is some suggestion from animal studies that PGE₂, PGE₁, and PGI₂ may be beneficial in response to sepsis through their endogenous counterregulatory properties. Administration of each of these has been shown to improve survival in several animal models of hypovolemic and traumatic shock, though clinical trials have failed to identify benefit.¹⁸¹ PGD₂ is a potent bronchoconstrictor that inhibits neutrophil chemotaxis and activation. TXA₂, PGG₂, and PGH₂ oppose the actions of prostacyclin by promoting platelet aggregation and inducing bronchoconstriction. TXA₂ produced by platelets and macrophages is a powerful vasoconstrictor that induces neutrophil accumulation and increases vascular permeability.^{177-179,182} There is substantial evidence that TXA₂ plays a significant role in early acute-phase organ injury.¹⁸¹

Lipoxygenase Pathway (Leukotrienes and Lipoxins)

LTs and lipoxins are leukocyte-derived molecules synthesized by the oxidation of arachidonic acid by three LO enzymes: 5-LO, 12-LO, and 15-LO (Fig. 7-10). 5-LO associates with the perinuclear membrane protein 5-LO-activating protein (FLAP) to catalyze the formation of 5-hydroperoxyeicosatetraenoic acid (5-HPETE). 5-HPETE is subsequently converted to LTA₄ by the combined efforts of a dehydrase and 5-LO. LTA₄ serves as the precursor for either LTB₄ or LTC₄. LTC₄ can in turn be successively hydrolyzed to the dipeptide derivative LTD₄ and the LTE₄. Additional LO activity results in the production of 12-HPETE, 12-HETE, and 15-HPETE. These compounds exhibit biological activity, although they are not as potent as the LTs or prostaglandins. The LTs are inactivated by oxidation followed by dehydration.^{178-180,182,183}

Figure 7-10. Eicosanoid production. 1. Phospholipases; 2. Cyclooxygenase; 3. Hydroperoxidase; 4. Thromboxane synthetase; 5. Prostacyclin synthetase; 6. E-isomerase; 7. D-isomerase; 8. F-reductase; 9. 5-Lipoxygenase; 10. Glutathione peroxidase; 11. Hydrolase; 12. Glutathione S-transferase; 13. γ -Glutamyl transpeptidase; 14. Cysteinyl glycine; 15. 12-Lipoxygenase; 16. Peroxidase; 17. 15-Lipoxygenase; 18. GSH-cis-11-trans lipoxin A₄; 19. α -Glutamyl transferase; 20. Dipeptidase.

The major LO product of neutrophils is LTB₄, though macrophages may also synthesize this compound. This compound is potently chemotactic for both neutrophils and eosinophils. By upregulating endothelial cell surface adhesion molecules it promotes leukocyte recruitment. It increases vascular permeability, either directly or through interaction with neutrophils and endothelial cells. LTB₄ has also been shown to induce hyperalgesia.^{94,180}

LTC₄, LTD₄, and LTE₄ comprise the family of slow-reacting substances of anaphylaxis (SRSA), compounds synthesized by mast cells during anaphylactic reactions. LTC₄ is the major eicosanoid product of eosinophils and the only mast cell–derived product of LO. These three LTs are potent vasoconstrictors and the most powerful bronchoconstrictors in humans, being three orders of magnitude more potent than histamine. They also increase vascular permeability and are vasodilatory in skin.^{43,180}

Lipoxins are biosynthesized by several routes in a tissue-specific manner. Current evidence implicates the eosinophil. A 5(6)-epoxytetraene intermediate can be formed by 5-LO activity on 15-HPETE. This reaction, when carried out in blood vessels, requires the interaction of platelets and neutrophils. On mucosal surfaces, 12-LO and 5-LO activity on LTA₄ can result in the formation of this lipoxin intermediate through leukocyte–epithelial interactions. The 5(6)-epoxytetraene intermediate is then converted to lipoxin A₄, lipoxin B₄, or lipoxin C₄, the last of which serves as the precursor for lipoxins D₄ and E₄.^{92,184,185}

Table 7-8 Prostanoid Effects

	PGG ₂	PGH ₂	PGI ₂	PGE ₂	TXA ₂

Platelet aggregation	↑	↑	↓	↓	↑
Systemic vascular resistance		↓	↓	↑	
Pulmonary vascular resistance	↑	↑	↓	↓	↑

PG, prostaglandin; TXA₂, thromboxane A₂.

Though many of the functions of lipoxins have yet to be elucidated, they appear to counterregulate the actions of LTs. They inhibit LT production by downregulating 5-LO as 15-LO is upregulated. The anti-inflammatory cytokines IL-4 and IL-13 further contribute to suppression of inflammatory responses by enhancing 15-LO activity. In addition to inhibiting synthesis, lipoxins inhibit the actions of LTB₄ and LTD₄. Lipoxins A₄ and B₄ are potent vasoactive compounds. Lipoxins influence smooth muscle and vascular tonus by increasing NO and prostacyclin production, increasing arachidonate release, and reversing endothelin-induced vasoconstriction. Counterinflammatory functions of lipoxin A₄ include inhibition of LTs, fMLP, and other chemoattractants. Lipoxin A₄ also downregulates LTB₄-mediated delayed type hypersensitivity reactions.^{92,184–186}

A large number of anti-inflammatory drugs, many of which are in clinical use, act by interfering with eicosanoid synthesis. The anti-inflammatory properties of corticosteroids are mediated at least in part by the inhibition of PLA₂ through the induction of lipocortin. They have been shown to selectively inhibit COX2 activation without affecting COX1. NSAIDS block the synthesis of both prostaglandins and thromboxanes by inhibiting COX activity. In contrast to the other NSAIDS, aspirin inhibits COX in an irreversible manner, and restoration of platelet function necessitates the administration of platelets. Aspirin, by either acetylating COX2 or by inducing the oxidation of arachidonic acid by cytochrome p450 or 5-LO, has been shown to stimulate the formation of 15R-HETE in endothelial or epithelial cells. These 15-epilipoxins exhibit higher potency in suppressing inflammation because of their prolonged half-lives. A potential complication of NSAID use and COX inhibition is the shunting of arachidonate through the 5-LO pathway and subsequent greater production of proinflammatory LTs (asthma). Such consequences minimize any benefit achieved from reducing other eicosanoid levels. In addition, NSAIDs act systematically in a nonselective manner, so that inhibition of prostaglandin synthesis can result in dangerous side effects in locations where prostaglandins normally exert cytoprotective effects (stomach).^{181,185,187}

PLATELET-ACTIVATING FACTOR

PAF is a heterogeneous mixture of 1-0-alkyl-2-acetyl-sn-glycero-3-phosphocholines that plays a

prominent role in both physiologic and pathologic inflammatory states. It does not exist preformed, but is rapidly produced by activated cells. Synthesis involves either the remodeling of membrane phospholipids by PLA₂, usually more important under inflammatory conditions, or by de novo synthesis as occurs in resting cells. De novo synthesis is regulated by substrate availability and involves a constitutively active enzyme that produces PAF in small basal amounts.¹⁸⁸ The membrane phospholipid precursor is present in high amounts in neutrophils. Other cells that can synthesize PAF include platelets, basophils, monocytes, eosinophils, mast cells, and vascular endothelial cells. Similar to eicosanoid production, the synthesis of PAF is initiated by calcium-dependent activation of PLA₂, which yields 1-O-alkyl-sn-glycerophosphocholine (lyso-PAF); subsequent acetylation generates PAF. PAF may be released from the cell, or it may be converted back to lyso-PAF by an acetylhydrolase and to the precursor ether-phosphatidylcholine.¹⁸⁸

The actions of PAF are mediated by G-protein activation. As the name implies, PAF induces platelet aggregation and degranulation; yet also possesses many other critical functions for inflammation. Its vasoactive properties include vasodilation and increased permeability, and it is an equally potent bronchoconstrictor. PAF enhances arachidonic acid metabolism, leading to increased leukocyte motility, degranulation, and free radical formation. PAF plays an integral role in promoting activation and adherence of inflammatory cells to the endothelium.¹⁸⁹ During the early inflammatory response, activated endothelial cells synthesize and express PAF on the cell surface. Leukocytes tethered by selectins to the endothelium are activated by endothelial PAF, which results in the induction of tight integrin-dependent adhesion and subsequent emigration and chemotaxis toward the inflammatory focus. Acyl-PAF, the major acetylated lipid from mast cells, basophils, and endothelial cells, is a less potent derivative of PAF that likely plays a similar role in the regulation of neutrophil recruitment. PAF also promotes platelet and neutrophil aggregation, thereby contributing to the prothrombotic state of acute inflammation. In circumstances of persistent pathologic stimuli, PAF may be liberated systemically, thereby causing the sequelae of an excessive inflammatory response. As a mediator of sepsis, PAF augments endotoxin-induced hypotension and neutrophil and platelet accumulation in the lungs. There is evidence that the NO-induced hypotension in experimental models of endotoxemia is mediated by PAF.¹⁹⁰ PAF infusion leads to a shock state that is similar to septic shock in that there is tissue hypoperfusion despite adequate fluid resuscitation. In animal studies, PAF has been shown to contribute many manifestations of sepsis including coronary vasoconstriction, reduced cardiac contractility, reduced preload, peripheral vasodilation, pulmonary vasoconstriction, increased microvascular permeability, gastrointestinal hemorrhage, and thrombocytopenia.¹⁸¹ Two prospective randomized, placebo-controlled trials of PAF inhibition in sepsis have suggested a benefit.¹⁸¹

PAF acetylhydrolase, an enzyme regulated by dexamethasone, estrogen, and PAF itself, is the enzyme responsible for degradation of PAF.

Kinins

Kinins (i.e., bradykinin and lysyl bradykinin) are small vasoactive peptides generated during the inflammatory response (Fig. 7-11). Three sources and mechanisms of kinin formation occur during inflammation: (1) plasma proteins; (2) tissue proteins; (3) cellular proteinases.¹⁹¹⁻¹⁹⁴

Production of Bradykinin

Biosynthesis commences with the activation of Hageman factor (HF), or factor XII of the coagulation cascade (Fig. 7-11). HF is activated by exposure to anionic surfaces such as the basement membrane of injured endothelium, heparin, or lipid A of endotoxin. It can also be proteolytically cleaved and activated by kallikrein. Prekallikrein circulates complexed with HMWK, a nonenzymatic protein. Kininogen enhances the binding of prekallikrein to negatively charged surfaces. Activated HF converts prekallikrein to kallikrein, which in turn activates more HF in a positive feedback cycle. HFf, a cleavage product of activated HF, is also capable of activating prekallikrein. Kallikrein in plasma, tissues, and secretions specifically cleaves HMWK to release the nonapeptide bradykinin. In addition to bradykinin production, kallikrein participates in the activation of plasminogen and C1q of the complement system; yet another link between inflammation and the coagulation system. The only major plasma inhibitor of activated HF is C1 inhibitor. The primary inhibitors of kallikrein in plasma are C1 inhibitor and α_1 macroglobulin.^{39,191}

Kinin Production in Tissue

Lysyl-bradykinin (kallidin) is the cleavage product of either HMWK or LMWK by tissue kallikreins,

which are proteins distinct from their plasma counterparts. LMWK is present in higher concentrations intracellularly compared with HMWK. Whereas both HMWK and LMWK can be converted to lysyl-bradykinin by tissue kallikrein, only HMWK is cleaved by plasma kallikrein. Kallidin itself can be converted to bradykinin by a plasma aminopeptidase. Both kallidin and bradykinin use the same receptors and perform similar functions, but kallidin is approximately 85% as potent as bradykinin. Tissue kallikrein is synthesized from a preproenzyme and is converted intracellularly to tissue Prekallikrein by enzymes that are not yet well-characterized. The secreted Prekallikrein is then converted to tissue kallikrein extracellularly by plasmin or plasma kallikrein. The only significant inhibitor of tissue kallikreins is α_1 -proteinase inhibitor.^{39,191}

Figure 7-11. Kinin pathway. (Modified from Proud D, Kaplan AP. Kinin formation: mechanisms and role in inflammatory disorders. *Annu Rev Immun* 1988;6:49.)

Cellular Kininogenase Activity

Neutrophils, mast cells, and basophils are sources of kininogenase activity. Neutrophils produce leukokinins by way of cathepsin D. Their role in inflammation is unclear. Bradykinin is metabolized sequentially to the partially active eight amino acid peptide, des-Arg-bradykinin, by carboxypeptidase N, and then to inactive five-amino acid and three-amino acid fragments by the angiotensin-converting enzyme (ACE). ACE is the predominant enzyme to inactivate bradykinin in the pulmonary vasculature. Arginine released as a byproduct of the carboxypeptidase N reaction may contribute further to the modulation of inflammation by acting as a substrate for the formation of NO.^{39,191,195}

There are three kinin receptors, of which two are well-characterized.^{191,193} B1 receptors are expressed primarily on the vasculature under pathologic conditions such as tissue injury. They bind des-Arg-bradykinin and des-Arg-kallidin and mediate the hypotension characteristic of sepsis and pain.^{191,196} Both B1 and the more widely distributed B2 receptors are G protein-coupled receptors. Activation of B2 receptors stimulates IP and PLC, resulting in the accumulation of the second messengers IP₃, DAG, and calcium. The B2 receptors are more important in mediating the effects of inflammatory kinins, such as bradykinin and lysyl-bradykinin. These kinins induce arteriolar dilatation and mediate pain. Similar to histamine, bradykinin increases the gaps between postcapillary venule endothelial cells leading to increase in vascular permeability. It is a potent constrictor of bronchial, uterine, and gastrointestinal smooth muscle, and the coronary and pulmonary vasculature.¹⁹³ Activation of endothelial B2 receptors stimulates production of NO to further enhance vasodilatation. Kinins have been implicated in mediating the antihypertensive and cardioprotective effects of ACE inhibitors.¹⁹⁷ ACE, in addition to catalyzing the formation of angiotensin II from angiotensin I, promotes the hydrolysis of bradykinin to inactive metabolites. In addition, bradykinin can modulate platelet function by stimulating endothelial cell secretion of PGI₂ and thromboxane through activation of PLA₂.¹⁹¹

Neuropeptides

Neuropeptides may provide a neuroendocrine link between psychological stress and inflammatory diseases such as psoriasis and inflammatory bowel disease. Like cytokines, their actions are pleiotropic

and redundant. Neuropeptides execute their inflammatory and immunomodulatory effect by binding to specific G protein–coupled receptors on the surfaces of target cells, and the resultant effect may be proinflammatory, anti-inflammatory, or both. For example, substance P mediates the hypothalamic fever response to PGE₂ induced by IL-1 and TNF α , whereas ACTH, AVP, and α -melanocyte stimulating hormone (α -MSH) suppress it. The pituitary peptides prolactin, CRH, and AVP have been shown to augment immune responses by enhancing T_H1 activity.^{39,198,199}

Tachykinins are important proinflammatory neuropeptides that mediate pain and vasodilatation and promote the classic inflammatory signs of erythema and edema. Substance P stimulates monocyte and neutrophil influx and neutrophil phagocytosis. Its inflammatory effects appear to be mediated by the proinflammatory cytokines TNF α and IL-1 from mast cells, monocytes, macrophages, bone marrow, and endothelial cells. During allergic inflammation, substance P stimulates histamine release from mast cells. As an effector of immune function, substance P promotes T-cell proliferation and antibody production. Substance P released locally by nerve terminals is important in mediating the perception of pain.^{39,191}

CRH induces the release of IL-1, IL-6, and superoxide anion from macrophages and negatively regulates its own proinflammatory effects through cortisol release. Cortisol downregulates production of proinflammatory cytokines such as IL-1, TNF α , and IL-2, metalloproteinases, and iNOS, and through this negative feedback loop, inhibits the production of CRH, ACTH, and AVP. AVP, growth hormone, and prolactin are other important proinflammatory neuropeptides.^{39,198,199}

Vasoactive intestinal peptide (VIP) and its homologues display both proinflammatory and anti-inflammatory effects. VIP is widely distributed throughout the central and peripheral nervous systems and serves as a chemoattractant for macrophages, neutrophils, and T cells, and may play an important role in granulomatous reactions. VIP stimulates the release of histamine and IL-5 and is a potent vasodilator. It inhibits IL-6, TNF α , and IL-12 release and iNOS expression in activated macrophages. VIP has also been shown to stimulate the production of the anti-inflammatory cytokine IL-10 by macrophages and to inhibit T lymphocyte proliferation and the production IL-2 and IFN- γ .²⁰⁰

Somatostatin and α -MSH are primarily anti-inflammatory in action. Somatostatin, which colocalizes with substance P in sensory nerves, inhibits IgE formation and NK cell activity, whereas α -MSH inhibits leukocyte chemotaxis, IFN- γ production, and downregulates T_H1 activity. ACTH, calcitonin, and β endorphin are other neuropeptides with predominantly anti-inflammatory properties.³⁹

Calcitonin gene-related peptide (CGRP) is an immunomodulator that inhibits the activity of T cells and macrophages, in part through the induction of IL-10. It also is an inhibitor of antigen presentation. CGRP promotes vasodilatation and neutrophil influx, and synergizes with bradykinin and histamine to promote edema formation.

Nitric Oxide

Endogenous NO was first discovered in 1987, and NO was the first gaseous molecule shown to be synthesized for the purpose of cell signaling.²⁰¹ NO is a weakly reactive radical that diffuses short distances from cell to cell independent of membrane channels or receptors. Its half-life is short because of its rapid inactivation by hemoglobin and other endogenous substances; thus, it functions primarily in a paracrine and autocrine fashion. The enzyme NO synthase (NOS) catalyzes the formation of NO and citrulline from the substrates L-arginine and oxygen.^{53,202–204} NOS contains prosthetic groups for flavin-adenine dinucleotide, flavin mononucleotide, tetrahydrobiopterin, iron protoporphyrin IX, and zinc. Three isoforms of NOS have been identified. The calcium-dependent constitutive isoforms, neuronal NOS (nNOS) and endothelial NOS (eNOS), generate the small amounts of NO necessary for those processes maintaining physiologic homeostasis, such as neurotransmission and endothelial regulation of vascular tone. The expression of inducible NOS (iNOS), however, requires stimulation and produces larger, sustained amounts of NO that possess both cytoprotective and cytotoxic properties. This distinction is not absolute, as certain cell populations express low basal levels of iNOS, and constitutive NOS transcripts can be enhanced by certain stimuli such as shear stress and hypoxia.^{53,202–204}

Many of the physiologic effects of NO are mediated by the activation of soluble guanylate cyclase. Increased levels of intracellular cyclic guanosine monophosphate trigger a reduction in calcium concentration and promote vascular smooth muscle relaxation and the inhibition of platelet aggregation and adhesion. The cellular response to NO also likely involves multiple signal transduction mechanisms, including the MAPK pathway.

Inflammation secondary to endotoxemia, hemorrhagic shock, and ischemia/reperfusion are associated with increased NO production by iNOS. First described in macrophages, iNOS can be expressed in

essentially any cell type in response to immunologic stimuli. Unlike nNOS and eNOS, iNOS does not depend on elevations in intracellular calcium levels for its activity.^{53,202–204} Important inducers of iNOS upregulation include LPS, IL-1, TNF α , and IFN- γ . Expression is primarily transcriptionally regulated, although stabilization of iNOS mRNA also appears to play a role. IFN- γ stabilizes iNOS mRNA, whereas TGF β can destabilize it. Transcription of the iNOS gene is controlled by NF κ B, IFN γ -responsive element, and TNF-responsive element. Induction of iNOS can be inhibited by glucocorticoids, thrombin, macrophage deactivation factor, PDGF, IL-4, IL-8, IL-10, and IL-13.^{53,202–204} Dexamethasone may inhibit iNOS induction by impairing the DNA binding capacity of NF κ B and by increasing levels of I κ B.^{205,206}

The endothelial dysfunction and vascular hyporeactivity that characterizes septic shock is consequential, in part, to iNOS production of NO.²⁰⁷ NO has been shown to be the effective mediator of the negative myocardial inotropy of TNF α , IL-6, and IL-2 and the TNF α -induced vasodilatation in the systemic and microcirculations.²⁰⁸ NO may indirectly increase prostaglandin production by increasing the catalytic activity of cyclooxygenase and decrease LT production by inhibiting 5-LO.²⁰⁹ NO plays an autoregulatory role in the T_H1 subset of T_H cells by limiting their own proliferation.²¹⁰

NO can mediate tissue injury in inflammation by modulating organ perfusion, mediating interactions with neutrophils, contributing to proinflammatory signaling, and by regulating apoptosis.²¹¹ Whereas eNOS primarily regulates perfusion during homeostasis, both eNOS and iNOS modulate organ flow in pathophysiologic states. Basal NO production from eNOS prevents the adherence of neutrophils to the endothelium and inhibits chemotaxis under physiologic conditions. Animal studies have demonstrated that pharmacologic inhibition of iNOS or genetic deletion of iNOS attenuates neutrophil accumulation in organs after ischemia/reperfusion injury.²¹² Conversely, similar experiments in endotoxemia implicate an antiadhesive role for iNOS, suggesting that the effect of induced NO on neutrophil accumulation is insult specific.²¹¹ Activated neutrophils can be stimulated by fMLP, PAF, LTB₄ to produce NO. NO produced by neutrophils at sites of inflammation can combine with superoxide to form peroxynitrite as another means of effecting toxicity.^{39,213}

The reaction of NO with superoxide is the only reaction that outcompetes the reaction of superoxide with superoxide dismutase. Small amounts of peroxynitrite are produced under basal conditions from constitutively produced NO and superoxide from mitochondria and other cellular sources. However, endogenous antioxidants such as GSH, vitamins E and C, and superoxide dismutase likely limit its toxicity. A low concentration of peroxynitrite has been shown to inhibit neutrophil adhesion. Higher concentrations of peroxynitrite can initiate a wide range of toxic oxidative reactions through a peroxynitrous acid intermediate. These include the initiation of tyrosine nitration, lipid peroxidation, and direct inhibition of mitochondrial respiratory enzymes. The balance between superoxide and NO determines the reactivity of peroxynitrite; excess NO reduces the oxidation elicited by peroxynitrite. In addition, peroxynitrite may contribute to cytotoxicity by a more indirect pathway. Peroxynitrite-induced single strand breaks in DNA activate the nuclear enzyme poly (ADP-ribose) synthetase, leading eventually to irreversible energy depletion of the cells and necrotic-type cell death.^{39,41}

Inducible NOS plays a key role in host defense, with NO or peroxynitrite exhibiting potent antimicrobial activity against a number of pathogens including viruses, fungi, and bacteria. Although microbicidal susceptibility to NO-mediated killing can vary considerably between species, essential roles have been identified in tuberculosis and bacterial peritonitis.²¹⁴ Induced NO has been shown to be essential for the upregulation of the inflammatory response in hemorrhage shock and other inflammatory processes. NO produced by iNOS leads to the activation of NF κ B.²¹⁵ This is followed by the induction of proinflammatory cytokines and increased leukocyte recruitment and activation.

NO possesses both proapoptotic and antiapoptotic effects depending upon the circumstances. NO derived from eNOS may inhibit apoptosis.²¹⁶ Proapoptotic effects appear to be associated with pathophysiologic conditions in which iNOS is upregulated. Low concentrations of peroxynitrite have also been shown to induce apoptosis, whereas higher concentrations promote cell necrosis in vitro. The role of NO-mediated apoptosis in the regulation of the inflammatory response is yet to be more clearly defined.

In summary, NO mediates tissue injury both directly through the formation of peroxynitrite, as well as, indirectly through the amplification of the inflammatory process. Like many mediators, NO has dual regulatory functions, and it is therefore difficult to characterize NO as distinctly proinflammatory or anti-inflammatory. In general, basal levels of NO produced by constitutive NOS may confer anti-inflammatory effects, whereas induced NO may tend to promote the upregulation of the inflammatory response. It is likely that an optimal level of NO is necessary in host defense; too little NO may be as harmful as too much.

Heme Oxygenase

HO catalyzes the breakdown of heme to iron, biliverdin, and carbon monoxide.²¹⁷ Three isoforms of HO have been identified. HO-2 is constitutively expressed in many tissues, whereas HO-3 expression appears to be limited to the brain. HO-1 is not expressed constitutively in most tissues, but is rapidly upregulated by both heme and nonheme cellular stresses, including hypoxia, redox stress, and inflammation. Additionally, NO is a potent inducer of HO-1. HO-1 has profound antiapoptotic and anti-inflammatory effects. These cytoprotective effects have been attributed to the individual catalytic products of heme metabolism. Biliverdin is converted to bilirubin by biliverdin reductase, and bilirubin has been demonstrated to act as a potent intracellular antioxidant. Carbon monoxide alone can mimic many of the actions of HO-1 and has been shown to protect in models of sepsis, hemorrhagic shock, and ischemia/reperfusion when administered as an inhaled gas. The mechanisms of action of carbon monoxide have both similarities and dissimilarities with NO, and is an area of active investigation.²¹⁷

Hydrogen Sulfide

Hydrogen sulfide is a colorless, flammable gas, with the typically malodor of putrid eggs. It is highly lipophilic and freely penetrates the cell wall, which greatly facilitates its biological activity.²¹⁸ Recent evidence highlights the widespread distribution of H₂S in the plasma, brain, and other tissues. H₂S is formed in mammalian cells largely by the activity of two pyridoxal phosphate-dependent enzymes, cystathione γ lyase (CSE), and cystathionine β synthetase (CBS) that utilize cysteine and homocysteine to form H₂S.²¹⁹ Large amounts of these enzymes occur in the brain (CBS), liver (CSE), kidney (CSE) and blood vessels (CSE). Interestingly, lipopolysaccharide exposure induces the expression of CSE, suggesting that H₂S may regulate inflammation.²¹⁸ Both pro- and anti-inflammatory actions have been described. H₂S levels and CSE expression are increased in animal models of endotoxemia, sepsis, and hemorrhagic shock.^{218,220,221} It has been shown to increase leukocyte attachment and rolling in jejunal blood vessels and to increase ICAM-1 expression.²²² In human monocytes, H₂S donors induce the formation of proinflammatory cytokines and chemokines via an NF κ B mechanism.²²³ Inhibitors of CSE reduce the inflammation in these animal models of sepsis and hemorrhage. By contrast, H₂S decreases LPS-induced upregulation of NF κ B in RAW 264.7 macrophages, and H₂S-releasing derivatives of diclofenac exhibit greater anti-inflammatory activity in endotoxic shock.^{218,219,224}

RECOGNITION AND ACTIVATION PROCESSES

Exogenous and Endogenous Danger Recognition

Multicellular organisms have evolved an essential mechanism of surveillance, defense, and repair of injured cells. Implicit with this system is the ability to differentiate pathogens and damaged cells from self. The initial response is orchestrated by the evolutionarily ancient and more universal innate immune system, which employs monoclonal sets of recognition molecules called PRR.^{225,226} PRRs bind conserved molecular structures found in large groups of pathogens, termed PAMPs. PAMPs are a diverse set of microbial molecules, which share a number of different recognizable biochemical features that alert the organism to intruding pathogens.^{225–227} These PAMPs are recognized by cells of innate and acquired immunity, primarily through the Toll-like PRRs. Activation induces several signaling pathways, most notably NF κ B.^{225,227} Consequent to this activation, an immune response is triggered to destroy the pathogen and/or pathogen-infected cells, and an adaptive response is initiated to select pathogen-specific T cells and antibodies for future occasions.

However, pathogens are not the only causative agents of tissue and cell damage. Cells, and thus tissues, can be injured by various noxious insults: heat, cold, chemicals, radiation, ischemia, or direct mechanical injuries. Evolution has enabled us to deal with these damages, which though not caused by pathogens, still necessitate repair. It is becoming apparent that specific receptors exist by which to recognize extrinsic threats (i.e., pathogen) and intrinsic altered self (cytokines, oxidized mitochondrial DNA, HSPs, and uric acid).²²⁷

Danger-Associated Molecular Patterns

8 DAMPs, the endogenous equivalent of PAMPs, represent danger signals or “alarmins” and share many characteristics similar to cytokines.²²⁷ DAMPs may be released following nonprogrammed cell death, such as necrosis, and under such circumstances tend to elicit inflammation. By contrast, programmed

cell death (i.e., apoptosis) incorporates mechanisms such as acetylation, to minimize the release of these mediators and any subsequent inflammatory response. Cells of the immune system also can be induced to secrete these mediators.²²⁷ This secretion may occur by specialized secretion systems or by the classical ER–Golgi secretion pathway.²²⁷ Under these circumstances, DAMPs may facilitate the inflammatory response by aiding the recruitment of innate immune cells, most notably DCs. In doing so, they indirectly orchestrate the subsequent adaptive immune response and facilitate tissue repair.²²⁷ The prototypical alarmin, HMGB1, has already been discussed.

S100 Proteins

The family of S100 proteins incorporates over 20 related calcium-binding proteins.²²⁷ S100A8 and S100A9 form heterocomplexes in the cytosol of granulocytes, monocytes, and macrophages, whereas S100A12 exists as homodimers in the cytoplasm of granulocytes. S100 proteins are actively secreted at sites of inflammation via a nonclassical pathway. The receptors mediating their effects are still being defined, though it appears that S100A12 and S100B interact with RAGE, whereas S100A8/9 may interact with TLR receptors. S100 proteins have been shown to induce increased vascular permeability and a prothrombotic effect. Recent studies implicate S100 proteins in the pathogenesis of autoimmune arthritis and psoriasis.²²⁷

Uric Acid

Uric acid is released after cellular injury, and upon exposure to the extracellular environment, precipitates to form monosodium urate (MSU).²²⁷ Uric acid stimulates dendritic maturation and, when coinjected with antigen in vivo, significantly enhances the generation of responses from CD8⁺ T cells.²²⁷ It has significant proinflammatory properties that are best evidenced in the disease gout, in which uric acid accumulates in tissues and induces inflammation-dependent arthritis. MSU crystals engage the inflammasome, resulting in the production of IL-1 β and IL-18.²²⁷ Macrophages from mice deficient in IL-1R or in various components of the inflammasome, such as caspase-1, ASC, and NALP3 are defective in MSU-induced cytokine secretion and have reduced inflammation.²²⁷ Extracellular uric acid is eliminated by uricase.²²⁷

Receptors for Danger Recognition

9 Innate immunity is not antigen specific, but rather programmed to respond to groups of evolutionarily conserved macromolecules that represent “patterns of danger” and signal a potential threat to the host. PRRs identify these PAMPs and include the TLR and NOD-like receptors. Recent studies highlight the promiscuity of these PRRs in also recognizing and mediating DAMP-dependent signaling. In fact, multiple positive feedback loops between DAMPs and PAMPs and their overlapping receptors may represent the molecular basis for the observation that infections, as well as nonspecific stress factors, can trigger flares of autoimmune diseases (i.e., rheumatic).¹⁴⁸ Additional novel receptors have subsequently been identified and designated PRRs, including RAGE.^{226,227}

CD14

The prototypical receptor identifying external infectious threat (i.e., gram-negative infection) is CD14. CD14 was identified as the LPS receptor when transfection of CD14-negative CHO cells with CD14 conferred responsiveness to LPS.²²⁸ Its critical role in LPS recognition is underscored by the LPS-hyporesponsive phenotype of CD14-deficient mice. It has been identified on cells of the myeloid lineage, B cells, liver parenchymal cells, and fibroblasts. Differential expression is observed; ranging from high levels on peritoneal and pleural macrophages to lower levels on Kupffer cells, alveolar macrophages, monocytes and PMN. Expression may be modified; human PMN express low levels of CD14 that is upregulated by TNF α , G-CSF, GM-CSF, and fMLP. Prototypically, CD14 binds LPS bound to LPS-binding protein (LBP) in combination with MD-2 and presents it to TLR4.²²⁸ MD-2 is required for cellular responsiveness to LPS, as demonstrated by both transfection studies and an analysis of a CHO cell line with mutated MD-2 gene. Most of the available evidence indicates that a complex of TLR4/MD-2/CD14 directly binds LPS.²²⁸ CD14 is also important in TLR2 signaling, whereby it presents bacterial products other than LPS.

Toll-Like Receptors

CD14 is a glycosylphosphatidylinositol-linked receptor devoid of any transmembrane domain. This, in combination with the identification of a soluble form of CD14, necessitated identifying the manner by which LPS induced activation.²²⁹ In 1996 the Toll protein in *Drosophila* was shown to be necessary for

an effective immune response to the fungus *Aspergillus fumigatus*.²²⁵ In 1998, Poltorak et al.²³⁰ discovered that the *lps* gene in LPS-hyporesponsive C3H/HEJ mice encoded a murine member of the TLR family. These data provided the initial evidence that mammalian TLRs function as PRRs. Subsequent studies have confirmed that TLR4 is the “LPS receptor” and that it is essential for the defense against gram-negative microorganisms.²²⁸

Thirteen mammalian TLR receptors have been characterized. Each recognizes a specific set of conserved microbial molecules, and as a family, they can detect most microbes.²²⁸ Interestingly, the subcellular localization of different TLRs correlates to some extent with the molecular patterns of their ligands and their function.²³¹ TLR1, TLR2, and TLR4 are located on the cell surface and are recruited to phagosomes after activation by their respective ligands. They are the receptors mediating the response to exogenous insults including bacterial infection and trauma. By contrast, TLR3, TLR7, and TLR9, all of which are involved in the recognition of nucleic-acid-like structures (i.e., viral DNA), are expressed intracellularly.^{225,232}

TLR4 is required for the innate response to gram-negative organisms and LPS, though other TLR, such as TLR2, can also recognize and mediate this response.²²⁶ TLR4 has been shown to trigger the response to additional ligands, including lipoteichoic acid (LTA) and peptidoglycans from gram-positive bacteria and the fusion protein of the respiratory syncytial virus.²³³ Polymorphisms in the receptor confer variability in function. Individuals with the D299G polymorphism in TLR4 demonstrate increased risk of gram-negative infections, and other studies have linked this with an increased incidence of SIRS.²³⁴ In addition, this polymorphism has been associated with alterations in the susceptibility to other inflammatory and potentially infectious processes (carotid artery atherosclerosis, coronary artery disease).²³⁴ HSP60 of Chlamydial origin has been found in atherosclerotic plaques and can bind TLR4. Perhaps recognition of HSP60 by human TLR4 might exacerbate the inflammatory component of atherosclerosis, whereas people with D299G polymorphism might be at least partly protected from this exacerbation.²³⁴ TLR4 has been well-characterized as a PRR for DAMPS, including HSPs (HSP60, HSP70, gp96), hyaluronate, heparan sulfate, and other matrix proteins. Because of its ability to recognize endogenous proteins, TLR4 is implicated in a variety of diseases, including arthritis and atherosclerosis.^{148,232}

TLR2 recognizes lipoproteins derived from the cell wall of bacteria such as *Treponema pallidum* and *Mycoplasma fermentans*, LTA from gram-positive bacteria (i.e., Streptococcal species), lipopeptides, LPS, and lipid A.^{226,232,233} It also can recognize a host of DAMPs, including the HSPs, fibronectin, fibrinogen, heparan sulfate and hyaluronate. Recent data suggest that TLR2 forms heterodimers with other TLR, including TLR1 or TLR6 to recognize these DAMPs. A likely consequence of this cooperation is an increased repertoire of ligand specificities. The R753Q polymorphism in the TLR2 is associated with decreased response to these bacteria and may increase susceptibility to staphylococcal infections or tuberculosis.^{232,234}

Additional TLRs involved in inflammation include TLR9, which recognizes unmethylated CpG motifs present in bacterial DNA. By contrast, most of the host mammalian genome is methylated. TLR9-ligand engagement occurs intracellularly, in either endosomes or lysosomes, presumably following bacterial lysis. Recent evidence suggests that TLR9 can identify host DNA released by dead or dying cells, and hence, may be involved in the autoimmune diseases such as SLE.²²⁵ TLR5 recognizes flagellin of bacterial flagella.²³⁵ TLR3 recognizes double-stranded RNA of both viral and endogenous sources. Because of the later characteristic, TLR3 has been implicated in autoimmune arthritis.

TLRs induce signal transduction via their cytoplasmic Toll-interleukin-1 receptor (TIR) domains that promotes the subsequent expression of a variety of host defense genes. These include inflammatory cytokines and chemokines, antimicrobial peptides, costimulatory molecules, MHC molecules, and other effectors. A considerable portion of the functional response is mediated by activating intracellular signaling pathways that culminate in the induction of the transcription factor NFκB. Specifically, the CD14/MD-2/TLR4 complex, upon engagement with LPS-LBP recruits the adapter protein MyD88, which engages the serine/threonine kinase IRAK. IRAK undergoes autophosphorylation and recruits TRAF6. Ultimately, activated IκK phosphorylates and targets for degradation the NFκB inhibitor IκB, which enables the nuclear translocation of NFκB and transcription of inflammatory genes. AP-1 and members of the MAPK transduction cascade are also activated by this mechanism. This pathway is critical to the production of IL-12, TNFα, and IL-6. All TLRs signal through this conserved signaling cascade, and for some MyD88 (TLRs 2, 6, 9) is their sole receptor-proximal adaptor. For instance, MyD88 is essential for clearance of *S. aureus*, a gram-positive bacteria, which signals through TLRs 2, 6, 9.^{225,226,233}

Subsequent studies utilizing MyD88-deficient mice suggested that alternate TLR pathways existed.

These mice, in response to many TLR ligands, including peptidoglycan and unmethylated CpG motifs, did not activate NFκB or MAPK. Surprisingly, however, LPS could still activate NFκB and MAPK, though in a delayed fashion. Subsequently, a MyD88-independent pathway has been characterized that is utilized by TLR4 and utilizes a distinct adaptor protein called TIR domain-containing adapter protein TIRAP or Mal. A dominant negative mutant of TIRAP specifically impairs TLR4- and TLR2- but not IL-1R or TLR9-induced NFκB, indicating a specificity of TIRAP for the TLR4 pathway. A third TIR-containing adaptor molecule, TIR-domain containing adaptor inducing IFN-β (TRIF) also appears to mediate a MyD88-independent pathway.^{225,226,233}

Most of this research has occurred in the realm of sepsis and provided insight into the manner by which organisms identify infectious threats and activate the inflammatory pathway to preserve the host. However, several circumstances of sterile inflammation suggest a role of the TLRs in mediating inflammation in response to endogenous danger signals (uric acid, mitochondrial DNA, HMGB1).²²⁸ Hepatocellular injury consequent to ischemia/reperfusion has been shown to be dependent on TLR4.³²

RAGE

RAGE is an immunoglobulin superfamily molecule that belongs to the multiligand receptors that recognize families of ligands rather than a single polypeptide.^{97,227,236,237} It has a single transmembrane spanning domain and a highly charged cytoplasmic tail that though lacking known signaling motifs, is critical for cellular activation. Though RAGE knockout mice are viable and fertile, they display a wide range of defects. Most of these defects are subtler than expected, leading to the suggestion that other receptors with overlapping function might exist. Signaling appears to necessitate clustering into a particular orientation, which facilitates binding of cytosolic signaling complexes.^{97,236} Its ligands include products of nonenzymatic glycosidation (e.g., advanced glycation endproducts or AGEs), the amyloid-β precursor protein, the S100/calgranulin family of proinflammatory cytokine-like mediators, and the high mobility group 1 DNA binding proteins (HMGB-1). Its expression is upregulated at sites of diverse pathologies including atherosclerosis and Alzheimer's disease. In fact RAGE-mediated cellular stimulation is thought to increase expression of the receptor itself, thereby generating a positive feedback mechanism and perpetuating the proinflammatory state.^{97,236,237}

Recent studies demonstrate the activation of multiple signal transduction cascades subsequent to ligand binding, including the family of MAPKs (p38, ERK 1/2, and JNK) and the rho gtpases (cdc42 and rac).²³⁷ Like TLRs and IL-1R, RAGE engagement leads to NFκB activation, suggesting that both receptor usage and signaling pathways evoke similar responses when cells are activated by PAMPs and DAMPs. It is currently hypothesized that RAGE–ligand interaction induces a new heightened basal state of activation. With a superimposed stimulus, cellular perturbation is magnified. Rather than returning to homeostasis, cellular signal transduction mechanisms favor augmented dysfunction.^{97,236}

Studies have implicated RAGE to be an important receptor during various acute and chronic inflammatory processes, including tumor biology. RAGE expression and function directly correlated with tumor growth in RAGE-transfected C6 glioma cells. In a murine tumor model, mice treated with soluble RAGE, which functions as a decoy, exhibited a reduction in lung metastases, cellular invasion, and expression of matrix metalloproteinases.²³⁷

RAGE has also been identified as a receptor for S100A12, a member of the S100/calgranulin family of proinflammatory mediators. Endothelial cells cultured with S100A12 displayed RAGE-dependent expression of VCAM-1 and tissue factor. Mononuclear phagocytes displayed S100A12-RAGE chemotaxis, expression of tissue factor, and elaborated IL-1 and TNFα. In vivo studies of delayed-type hypersensitivity demonstrated reduced inflammatory response when mice were treated with anti-RAGE F(ab')₂, anti-S100 F(ab')₂, or soluble RAGE. Treated animals also displayed reduced NFκB activation and IL-1 and TNFα expression.²³⁷

The angiopathy of diabetes is thought to be consequent to inflammatory processes generated by elevated glucose concentrations. Hyperglycemia has been demonstrated to activate numerous signaling cascades. One process that might mediate these effects is through the nonenzymatic formation of AGEs.^{97,236,237} AGE-RAGE interactions on endothelium lead to the expression of procoagulant tissue factor and VCAM-1 and macrophages-released tissue factor. Animals treated with soluble RAGE showed decreases in atherosclerotic lesion area and number and a marked reduction in lesion complexity. Also, treated animals had reduced expression of adhesion molecules, tissue factor, MCP-1, and matrix metalloproteinases.^{97,236,237}

CD91

The immunological properties of HSPs were discovered by their ability to elicit antitumor immunity. It

was later discovered that this antigenic specificity was determined by the peptides they chaperoned. APCs can bind and internalize HSP–peptide complexes derived from virus-infected cells or tumors and represent them on major histocompatibility MHC class I molecules. In addition, APC engagement of HSP–peptide complexes induces maturation, the expression of costimulatory molecules, and the induction and release of cytokines (TNF α , IL-1, IL-12, IL-6, GM-CSF, MIP-1, RANTES, and NO).^{238,239}

CD91 had been identified as a receptor for the serum protein α_2 macroglobulin, a natural protease inhibitor that like HSPs is found across many species. In fact α_2 macroglobulin is the evolutionary precursor of the C3 complement component. By binding pathogen proteases utilized during invasion and shuttling them for endocytosis, α_2 macroglobulin hinders pathogen invasion.^{238,240}

However, such a method of host defense would be ineffective for intracellular pathogens that gain access by alternative means, such as mimicking host proteins and developing ligands for host receptors. Hence, another method for signaling danger is necessary. It is currently thought that upon cell death, HSPs contained within the cell transfer information regarding the infected intracellular environment to CD91. This large cell surface receptor, complexed with the HSPs, is internalized and delivers antigen to the classical MHC class I pathway. The MHCs bind and present them to CD8⁺ T cells. On recognizing nonself, T cells are induced to proliferate and mediate killing. This mechanism could be generalized to implicate CD91 and HSP interactions in the recognition of all cellular stress that culminates in injury and death.²⁴⁰

CD91 was first identified by Binder et al. as the receptor for gp96 and then by Basu et al. as a common receptor for other HSPs (HSP70, HSP90, and calreticulin).^{241,242} This large multidomain 600-kD protein possesses multiple binding sites for at least 32 ligands. The binding of this receptor to many members of the HSP family has been corroborated by several independent functional and structural studies.²⁴⁰

Several in vivo studies suggest a physiological relevance for HSP-CD91 interaction. Mice immunized with tumor-derived gp96–peptide complexes reject a subsequent tumor challenge. If CD91 antiserum is mixed with the HSP–peptide inoculum, the mice fail to reject the tumors. Srivastava et al. noted that blocking of CD91 completely inhibits the phenomenon of representation of peptides that are carried or chaperoned by HSPs, suggesting that not only is CD91 a receptor for HSPs, but it may also be the sole receptor involved in antigen representing.^{239,242}

Figure 7-12. Autophagy/mitophagy. Autophagy is inhibited by the metabolic growth rheostat mTOR that inhibits autophagy when ATP and nutrients are plentiful. Sepsis and metabolic stress lead to inhibition of mTOR and initiation of the isolation membrane. Atg12-ATG5-Atg16L and LC3-II localize to the phagophore to capture selected targets for degradation. Upon completion of autophagosome formation, the Atg12-Atg5-Atg16L complex dissociates while LC3-II remains on it. The autophagosome ultimately fuses with the lysosome to form an autolysosome, where its contents are degraded.

HSPs have been shown to chaperone antigenic peptides (tumor, viral, minor histocompatibility antigens) from all cellular compartments. The family of HSPs thus appear to be a universal mechanism for antigen capture, and they permit a high-efficiency antigen uptake through a receptor-mediated mechanism.

Evidence that HSP–peptide–CD91 interactions serve to signal cellular stress is beginning to culminate. Basu et al. demonstrate that Hsp70, Hsp90, gp96, and calreticulin are released from cells as a result of necrotic cell death, but not apoptotic cell death.²⁴¹ Similarly, Melcher reported that tumor cells undergoing necrotic death are highly immunogenic as compared to those undergoing apoptotic death.²⁴³ Actual necrosis may be unnecessary as stressed cells and cancer cells have been reported to express cell

surface HSP molecules, which may activate APCs. Li et al. observed that physical contact of tumor cells artificially engineered to express cell surface HSPs with immature DCs elicits a powerful maturation of DCs.²⁴⁴

Other HSP Receptors

CD40 was reported as a receptor for Hsp70 when anti-CD40 antibodies were observed to inhibit macrophage chemokine secretion in response to mycobacterial Hsp70. Subsequently, Becker noted the association of recombinant GST-tagged CD40 with murine Hsp70.^{245,246} They further demonstrated enhanced binding after the APCs were stimulated with LPS. As LPS induces expression of a number of cell surface molecules, the authors concluded that CD40 mediates recognition and binding of Hsp70.²⁴⁷

CD36 has been implicated as a receptor for gp96. Transfection of CD36 into CD36-negative cells has been shown to enhance gp96 binding. In addition, CD36^{-/-} macrophages have a 52% reduction in gp96 binding compared with wild-type controls, suggesting that some role for CD36 as an Hsp receptor.²⁴⁷

LOX-1, a member of the same scavenger superfamily as CD91 and CD36 has been postulated to be an additional receptor for endocytic uptake of Hsp70 and chaperoned peptides by human DCs. Anti-LOX-1 antibodies and LOX-1 ligand-acetylated albumin competed with Hsp70 for binding to DCs.¹¹⁴

Both TLRs and CD14 have been implicated as receptors for HSPs, such as Hsp70.²⁴⁸ Hsp70 stimulates macrophage IL-12p40 production that is partially abrogated by inhibiting downstream TLR signaling cascades. In addition, human Hsp60 activated NFκB and TNFα production by 293T cells transfected with either TLR-2 or TLR-4 and MD-2.²⁴⁹ Hsp60 also activated JNK kinase and IKK kinase signaling and TNFα production by macrophages, an effect that was partially eliminated by knocking out MyD88 or TRAF6. Similar functional studies have proposed that CD14 might serve as an Hsp70 receptor in APCs. All of these studies heavily suggest a role of TLRs or CD14 in HSP binding, although several investigators call into question the potential for contamination with LPS to be mediating much of these effects.²⁴⁷

AUTOPHAGY

Autophagy is an ancient cytoplasmic homeostatic process governing cellular biomass quantity, quality, and distribution through the recycling of cytoplasmic proteins and organelles to support vital functions during periods of stress (i.e., starvation).^{250,251} It literally originates from the Greek words *auto* meaning “self” and *phagein* meaning “to eat.” Fundamental for embryological development and survival, it integrates extensively with apoptosis and may itself function as a form of programmed (type II) cell death.^{251–253} Hence, it is not surprising that it is preserved in all eukaryotic organisms, from yeast to humans.

Macroautophagy is coordinated by specialized autophagy-related proteins (ATGs) that sequester large protein aggregates, dysfunctional organelles, and even microorganisms and target them for lysosomal degradation. In the setting of nutrient deprivation, the mechanisms orchestrating this dynamic process involve the main growth rheostat mammalian target of rapamycin (mTOR) and adenosine monophosphate (AMP) kinase, a sensor of cellular energy status.^{251,252,254–258} Prototypically, AMP kinase, sensing reduced cellular energy (i.e., elevated AMP) inhibits mTOR, a negative regulator of autophagy, thereby inducing autophagy.^{252,254,259,260}

Autophagy is initiated by complex formation of ULK1 and ULK2, the class III phosphatidylinositol-3-phosphate kinase VPS34, and ATG14-like protein, ATG14L. This initiates the ATG conjugation cascade in which ATG5 and ATG12 complex with ATG16L1 to form an isolation membrane around the target (Fig. 7-12). The complex facilitates the addition of a phosphatidylethanolamine group to LC3-1 to form LC3-II. LC3-II together with other factors leads to elongation and closure of the autophagosome, which is then targeted for fusion with the lysosome, forming the autolysosome (Fig. 7-12).

Though the quintessential function of autophagy is to digest and recycle portions of the cytoplasm during starvation, it has recently been described as an important effector arm of immune cells responding to exogenous (i.e., PAMP: LPS)^{261,262} and endogenous (DAMP: HMGB1) stimuli.^{250,259,262–266} It is proposed that competition with microorganisms for nutrients, and thus nutrient deprivation, may have served as a sign of invading organisms and thereby supported the emergence of eukaryotic autophagic mechanisms of pathogen elimination. However, a host of other PAMPs and DAMPS and mediators may induce autophagy. In Mφ, LPS induces autophagy through mechanisms dependent on TLR4, TRIF, RIP1, and p38 MAPK.^{261,267} Cytosolic pathogens, such as viruses, can induce autophagy, or rather xenophagy. DAMPS, such as DNA, ATP, and HMGB1 may also induce autophagy, the later

through RAGE. The induction of autophagy by the inflammatory cytokine IL-1 β is critical for control of *Mycobacterium tuberculosis*. Similarly, TNF α stimulates autophagy in restricting intracellular bacteria. By contrast, T_H2 cytokines such as IL-4 and IL-13 and NO inhibit autophagy.

During innate immunity, autophagy has been shown to be important in the elimination of intracellular microbes, through LC3-associated phagocytosis and xenophagy. This latter process of selectively degrading intracellular pathogens involves sequestosome 1-like receptors (SLRs) that recognize molecular motifs on invading pathogens. These SLRs help to clear microorganisms that gain entry to the cytoplasm if they escape the defenses that are controlled by conventional PRRs. Microbial polymers, such as DNA, that are present in the cytoplasm might function as autophagy-inducing PAMPs, as in the case of *M. tuberculosis* infections. The critical importance of autophagy to cell survival is perhaps best made evident by the defenses several microbes (*Listeria*, *Shigella*, *Legionella*) exhibit to combat autophagy machinery.

Autophagy can assist PRR by delivering cytosolic PAMPs to endosomal TLR (i.e., TLR7) and stimulate their activity.^{268–270} Nucleic acid receptors called RIG (retinoic acid inducible gene)-I-like receptors (RLRs) recognize viral RNA, and induce the production of type I IFN to thwart viral invasion. The interaction between TLRs and autophagy may also serve to augment antigen presentation by DCs.

Autophagy limits the activation of the inflammasome, a cytoplasmic complex that responds to PAMPs and DAMPs by inducing the proteolytic processing and secretion of IL-1 β and IL-18. It does so by clearing the cytoplasm of debris, such as damaged or depolarized mitochondria that can function as endogenous agonists. Inhibition of autophagy leads to the release of the products, such as mitochondrial DNA and ROS.^{268–270} Autophagy also affects the secretion of pro- and anti-inflammatory mediators. In senescent cells, it regulates the secretion of IL-6 and IL-8. It reduces immunoglobulin secretion from plasma cells, and thus, may be important in negatively regulating antibody production.

During adaptive immunity, autophagy contributes to MHC class II presentation. Classically this is described in the context of presenting cytoplasmic antigen (e.g., virus or self antigen) to endosomal receptors, such as TLR7 (see above). Thus, autophagy is implicated in autoimmune disorders such as autoimmune colitis and Crohn's disease. The link between autophagy and inflammatory diseases has also been reported. Polymorphisms in ATG16L1 and IRGM are linked to Crohn's disease. IRGM polymorphisms may be a risk factor for SLEs, and rheumatoid arthritis has been associated with variations in the ATG5 gene. In summary, autophagy influences adaptive immune responses through its effects of antigen presentation, naïve T cell-repertoire selection, T-cell homeostasis and T_H-cell polarization.^{268–270}

Interestingly, nonimmune cells, such as hepatocytes and renal tubular cells also exhibit TLR signaling and respond to the stress of sepsis or lipopolysaccharide by inducing autophagy.^{32,264,271–274} Studies suggest that these mechanisms are similarly induced in vivo in the early response to sepsis, and regulate bronchoalveolar cytokine/chemokine production and neutrophil accumulation. Others have shown that sepsis induces similar AMPK- and mTOR-dependent mechanisms of autophagy in the M ϕ , kidney, and liver.^{267,271,275–277} This mechanism may be critically important for cell survival, as it has been shown that augmenting mTOR- or AMPK-dependent autophagy during CLP sepsis attenuates mitochondrial injury and reduces acute kidney injury (AKI) (Fig. 7-6).²⁷⁴ In summary, recent data support a fundamental role of autophagy in nearly every arm of immunity as an antimicrobial effector of TLR.^{253,264,265,267,268}

Mitophagy, autophagy directed at the removal of damaged mitochondria, is considered to of particular importance in protecting against organ injury, such as AKI.²⁷⁸ At least two mechanisms are involved in the sequestration and elimination of defective mitochondria: Atg7 and PINK1/Parkin. Atg7 is an autophagy protein that is required for the initiation of ubiquitin-like conjugation pathways of autophagy. During erythroid maturation, Atg7 serves a nonredundant role in mitochondrial clearance through canonical autophagosomal pathways.^{279,280} Alternatively, PINK1 accumulation at the outer mitochondrial membrane of dysfunctional mitochondria selectively recruits Parkin, which in turn promotes their selective degradation by mitophagy.^{281–284} Conditions that induce mitochondrial dysfunction and depolarization strongly induce this pathway, which is important for cell survival.²⁸⁵ Indeed, endogenous Parkin production and exogenous Parkin overexpression have been found cytoprotective in different conditions of stress, including sepsis. Not surprising, due to the potential for release of cytochrome C and ROS, it is vital that a cell possess a programmatic mechanism for the elimination of defective mitochondria.

THE STRESS RESPONSE

The stress response is the cellular reaction to any perturbation or disruption in equilibrium and serves to restore homeostasis. Inducers of the stress response include physical stresses (burns, radiation, trauma), chemical agents and mediators (toxin, heavy metals, cytokines, ROS), infectious agents (bacteria, viruses, parasites), and allergens. It is often referred to as the heat-shock response after the identification in the 1960s of the HSPs, a group of genes expressed after exposure to heat.²⁸⁶ However, subsequent investigations delineated additional cellular proteins that are expressed in response to a wide variety of insults. Clinically, expression of HSP has been observed under conditions in which oxygen delivery is compromised, as in hemorrhage or ischemia.²⁸⁷

Activation of the stress response is characterized by both morphologic and metabolic cellular alterations. Morphologic alterations include the accumulation of unprocessed forms of mRNA in the nucleolus, and increased numbers of actin microfilaments in the cytoplasm. Changes in cellular metabolism include a rapid reduction in intracellular ATP levels, most likely correlated with alterations in the integrity of mitochondria. The stress response is characterized by transient downregulation of most cellular products and by the upregulation of stress proteins.²⁸⁸ It is the induction of stress proteins that confers the primary adaptive and protective effects of the stress response.

After expression of stress genes, cells become resistant to subsequent stresses. Members of the stress protein family include HO (see above); the multiple-drug resistance gene product P-glycoprotein; ubiquitin, involved in targeting proteins for degradation; scavengers such as superoxide dismutase, ferritin, and metallothioneins; and the glycolytic enzymes enolase and glyceraldehyde 3-phosphate dehydrogenase. The most extensively characterized are the HSPs.³⁹

HSPs are molecular chaperones that may either be constitutively expressed or induced upon cellular stress.²⁸⁹ Classification is based upon their molecular mass and degree of homology. The most extensively studied is the Hsp70 family, members of which possess a mean molecular mass of 70 kD and greater than 70% homology. Members of the Hsp70 family bind ATP, and are induced under conditions of energy depletion and stress. Hsp70 is integral in cellular adaptation to and survival during environmental stresses. Both Hsp72 and Hsp73 are present in the cytosol and nucleus. The former is constitutively expressed, whereas, expression of Hsp72 is exclusively induced. In most studies Hsp72 is used as a marker of HSP induction.^{39,287,290,291}

The Hsp60 family members are also referred to as chaperones. The glucose-regulated protein group of HSP is induced with glucose starvation, inhibitors of N-glycosylation, and calcium ionophores. The decrease in glucose content may affect the pool of sugar donors during protein glycosylation. The low-molecular-weight HSP (molecular masses of 20 to 30 kD) may be important regulatory components of the actin-based cytoskeleton.²⁸⁷

HSP regulation of transcription occurs through the activation of heat-shock elements in the gene promoters. Two heat-shock transcriptional factors (HSF) have been identified, HSF1 and HSF2. HSF1 activates transcription of the Hsp72 gene in response to heat, heavy metals, and other inducers of the stress response. With stimulation, unbound HSF1 oligomerizes, translocates to the nucleus, and binds to the HSP promoter to activate the transcription of the gene. HSF2 is not activated by the classic inducers of heat-shock genes, but may be important in controlling the activities of HSP gene expression in the normal or unstressed cell.^{39,287,290,291}

HSP can play multiple roles in modulating the inflammatory response. A number of conditions such as rheumatoid arthritis, ARDs, and asthma have been shown to benefit experimentally from increased HSP expression.^{286-288,291} Functions of HSP include enhancement of immune responses, thermotolerance, regulation of apoptosis, hemostasis, and cytoprotection against ROS and other inflammatory mediators. HSP-CD91 interaction is integral to the processing and representation of antigen by APCs. HSP may shift the balance between T_H1 and T_H2 toward an increase in more anti-inflammatory T_H2 cells. ROS, including H₂O₂, hydroxyl radical, and peroxynitrite, activate HSP synthesis. In the presence of iron, ROS also induce the oxidation-specific stress proteins HO and ferritin, which afford protection against oxidative stress by binding iron and preventing it from participating in the Fenton reaction. Mechanisms of HSP-mediated cytoprotection from the toxic effects of ROS include the maintenance of cellular GSH levels (Hsp27) and mitochondrial protection (Hsp70). Hence, ROS induce a cytoprotective response that counteracts their own toxicity. Other inflammatory mediators such as NO have also been shown to induce expression of HSP.³⁹

HSP may participate in intracellular signaling pathways that modulate the production or function of inflammatory mediators. For example, Hsp90 has been shown to facilitate signaling that leads to NO

formation by eNOS.²⁹² Hsp70 has been reported to prevent apoptosis, which may promote propagation rather than resolution of inflammation. In addition, the body's immune response to bacterial and parasitic stress proteins likely protects the host from infection. The bacterial homologue of Hsp60, GroEL, is a major target of the mammalian humoral response to bacterial infections. Many activators of HSF1 are potent inhibitors of the proinflammatory transcription factor NFκB. Aspirin and other NSAIDs activate HSF while inhibiting NFκB. Therefore, the anti-inflammatory effects associated with the stress response might be related more to the inhibition of NFκB activation.^{287,293}

The Acute-Phase Response

The acute-phase response consequent to trauma or cellular injury is characterized by alterations in hepatic metabolism; activation of the central nervous system, leading to fever and adaptive behaviors; altered hematopoiesis; activation of complement and the fibrinolytic and coagulation cascades; and the release of neuropeptides, kinins, and hormones. It is a rapid, nonspecific response that accompanies both acute and chronic inflammatory disorders. Many of the processes induced during the acute-phase response are mediated by cytokines. IL-6, IL-1, and TNF α play particularly central roles.^{294,295} Though considered a defense mechanism promoting host survival, aberrant or unregulated production of many of these inflammatory mediators can be lethal.

Acute-Phase Proteins

An acute-phase protein is defined as a protein whose concentration increases by at least 25% during inflammation (Table 7-7).^{295,296} These changes are primarily due to altered hepatic synthesis and typically occur within approximately 6 hours of the inciting stimulus. The function is to restore homeostasis: hemostatic functions (fibrinogen), microbicidal and phagocytic functions (complement components, C-reactive protein [CRP]), antithrombotic properties (plasminogen, protein S), antioxidant properties (haptoglobin), and antiproteolytic actions (α_2 macroglobulin, α_1 protease, α_1 chymotrypsin). The negative acute-phase proteins albumin, prealbumin, transferrin, and retinol-binding protein decrease by at least 25%. Levels of the negative acute-phase proteins, albumin and transferrin, drop almost immediately after operation and remain depressed for several days. The rapid initial loss of these proteins is likely due to increased vascular permeability and loss to the extravascular space. The magnitude of the response is proportional to the severity of the stress. Whereas trauma and burns lead to significant increases in acute-phase reactants, exercise and psychiatric illness induce more moderate responses.

The two major acute-phase proteins in humans are CRP and serum amyloid A (SAA). CRP, named because of its reaction with pneumococcal C-polysaccharide, displays both proinflammatory and anti-inflammatory effects. It has been shown to activate complement, recognize foreign pathogens, bind phagocytic cells, and enhance activation of tissue factor, the main initiator of coagulation. CRP can also inhibit superoxide production by neutrophils and inhibit neutrophil adhesion by decreasing surface expression of L-selectin. Changes in plasma or serum CRP, although nonspecific, may reflect the magnitude of an inflammatory process and may aid the differentiation of inflammatory from noninflammatory conditions. Measurement of CRP is more precise than the erythrocyte sedimentation rate; the latter largely depends on plasma fibrinogen levels and is influenced by a variety of other, unrelated factors in the circulation. SAA may promote chemotaxis and adhesion of phagocytes during inflammation.³⁹

C1 inhibitor is of special interest as an acute-phase protein because of its effects outside of the complement cascade. This antiprotease inhibits the activity of HF, limiting kinin production and factor XI production. Thus, enhanced expression of a complement inhibitor protein during acute inflammation may also influence coagulation, fibrinolysis, and kinin pathways.

Systemic Manifestations of the Acute-Phase Response

Systemic manifestations include neuroendocrine changes, shifts in the hematologic profile, and metabolic and chemical alterations. The classic neuroendocrine manifestation is fever. IL-1, IL-6, and TNF α mediate the fever response by resetting the hypothalamic temperature setpoint through the synthesis of PGE₂. The secretion of neuropeptides, such as CRH and AVP, and of hormones, such as glucagon, insulin, thyroxine, and aldosterone, is also characteristic of the acute-phase response. CRH and AVP are released by the hypothalamus and increase ACTH and cortisol levels. The rise in plasma cortisol levels occurs rapidly and may function to inhibit the fever response and cytokine gene expression, thereby serving a potential negative regulatory function in the acute-phase response. Glucocorticoids also stimulate macrocortin synthesis, which by inhibiting synthesis of PLA₂, limits the availability of arachidonic acid for prostaglandin synthesis. Glucocorticoids increase the rate of synthesis of certain acute-phase proteins involved in connective tissue repair and clotting, as well as antioxidants and antiproteases. They also may function to counteract the hypoglycemic response to insulin overproduction during infection or stress.

Other alterations include a prominent leukocytosis, thrombocytosis, and the “anemia of chronic disease.” Metabolic changes include altered lipid metabolism and negative nitrogen balance. Changes in

the chemical and enzymatic profile include increased hepatic production of metallothionein, iNOS, HO, manganese superoxide dismutase, and glutathione (GSH). Plasma levels of zinc and iron are noted to drop, whereas copper levels increase slightly. This persists for the duration of inflammation and is likely due to sequestration induced by IL-6, glucocorticoids, and catecholamines. Low levels of iron and zinc may confer protective antimicrobial effects because they are essential micronutrients for microbial growth.³⁹

Mediators of the Acute-Phase Response

Bacterial products such as LPS are probably the most potent activators of tissue macrophages, the initiators of the acute-phase response. LPS, through its interactions with LBP, CD14, and TLR, induces macrophage synthesis of ROS, including NO; lipid derivatives (e.g., PGE₂, thromboxane A₂, and PAF); and acute-phase cytokines (e.g., TNF α , IL-6). Additional mediators inducing the synthesis of acute-phase cytokines in the absence of bacterial infection include free radicals, prostaglandins, and the release of DAMPs from injured tissues.³⁹ Indeed the response to the sterile insult of trauma mirrors much of what is observed during severe sepsis, a similarity that may be the consequence of substantial overlap in signaling mechanisms, such as TLR4.

Acute-phase cytokines can be proinflammatory (IL-1, TNF α , IFN γ , IL-8) or anti-inflammatory (IL-10, IL-4, IL-13, TNF β). However, it is IL-6 and IL-6-type cytokines that are most critical in the acute-phase response. IL-6 is the major inducer of acute-phase proteins synthesis and, together with IL-1 and TNF α , is responsible for the systemic features classically associated with the acute-phase response (fever, anorexia, leukocytosis, and hormonal changes).³⁹

In addition to the aforementioned cytokines, IFN γ is a potent inducer of complement components. The anti-inflammatory cytokine TGF β stimulates synthesis of antiproteases, urokinase, and negative acute-phase proteins. IL-4 is inhibitory to some acute-phase proteins. Growth factors, including hepatocyte growth factor and TGF β are also able to modulate the synthesis of acute-phase proteins. Glucocorticoids augment the response to cytokines, and insulin attenuates the cytokine-induced rise in acute-phase proteins.³⁹

Effects of the cytokines are influenced by cytokine receptors, receptor antagonists, and hormones. IL-1RA competes with IL-1 and attenuates the acute-phase response in vivo. Soluble receptors for IL-1 and TNF α act as antagonists. In contrast, soluble receptors for IL-6 act as agonists.

Regulation of Acute-Phase Cytokines and Proteins

Several major families of transcription factors participate in the upregulation of acute-phase cytokines and proteins, the most important being NF-IL-6, AP-1, and NF κ B.²⁹⁷ NF-IL6 participates in the expression of the cytokines IL-1, TNF α , IL-6, and IL-8. Activation through the NF κ B is probably the predominant pathway. The triggering of IL-6 in monocytes in vitro by IFN γ involves a change in the amount of the phosphorylated transcription factor Sp1, together with the induction and activation of IFN-regulatory factor.

All known acute-phase proteins are regulated primarily at the transcriptional level. Activation of TNF α and IL-1 receptors triggers signaling pathways that activate transcription factors AP-1 and NF κ B. Many type I acute-phase proteins genes contain response elements for NF κ B, NF-IL6, and AP-1. Acute-phase protein responses to IL-6 are mediated through the JAK-STAT signal transduction pathway. In addition, both IL-1 and IL-6 signal transduction mechanisms activate the MAPK pathway that activates transcription factors NF-IL6, linking the IL-1 and IL-6 pathways.

Reperfusion Injury

Prolonged tissue ischemia produces irreversible injury and cell death. Timely restoration of perfusion may salvage some tissue, though paradoxically can induce injury as well. Reperfusion injury is the damage caused by the restoration of blood flow in previously ischemic tissue (i.e., myocardial ischemia, transplantation, vascular surgery). Injury is the direct consequence of activation of the inflammatory response, especially complement activation and neutrophil recruitment. Components of the complement cascade promote tissue damage through the generation of anaphylatoxins and by the formation of the MAC. Invading neutrophils injure tissue through the generation of ROS and the release of proteolytic enzymes. Recent evidence points to TLR4 as a sensor of tissue stress, the signal of which is probably through release of DAMPs from ischemic cells.³²

Alterations in the microvascular endothelium are central to the pathophysiologic process of reperfusion injury. Early loss of constitutive NO production facilitates neutrophil adherence, the

upregulation of cell adhesion molecules such as P-selectin, and inhibits vasorelaxation and perfusion.²⁹⁸ Low oxygen tension induces the conversion of xanthine dehydrogenase to xanthine oxidase. Reperfusion and reoxygenation yield the formation of superoxide anion and H₂O₂ and induce oxidant injury. Neutrophils and other cellular effectors are progressively recruited and activated, releasing ROS, cytokines, and NO, further contributing to increased vascular permeability and tissue injury. PAF released by neutrophils activates circulating platelets and promotes vascular plugging. Platelets also release factors that enhance platelet–neutrophil adhesion. Both cell types also release vasoconstricting agents that can further exacerbate no-reflow. Capillary plugging by neutrophils and platelets can impair local blood flow and cause the “no-reflow phenomenon.”³⁹

Neutrophils mediate direct toxicity to the surrounding tissue through the elaboration of ROS and granule contents. Peroxynitrite formed by the reaction of NO and superoxide can contribute directly to tissue injury during reperfusion. Neutrophil granule proteases such as elastase, collagenase, and gelatinase alter the vascular permeability and are highly destructive to local tissue. The significance of the neutrophil in mediating these effects are apparent in neutrophil depletion studies demonstrating attenuated tissue injury when compared to subjects with normal numbers of neutrophils.²⁹⁹ Animal studies using blocking monoclonal antibodies to selectins and β_2 integrins show improved organ function ischemia/reperfusion.³⁰⁰

The mechanism by which complement is activated with reperfusion is not completely understood. Ischemia may alter the cell’s plasma membrane or through the exposure of basement membrane or subcellular organelle components, creating a complement-activating surface. Alternatively, binding of natural antibody may lead to induction of these cascades.¹⁷² Complement activation has been shown to occur in the setting of therapeutic thrombolysis. The generation of plasmin-dependent fibrinolytic agents and plasmin after tissue plasminogen activator administration has been associated with complement activation.³⁰¹

Anaphylatoxins are important effectors of complement-mediated injury. They alter vascular permeability, induce smooth muscle cell contraction, and stimulate the release of histamine from mast cells and basophils. C3a and C5a are potent chemoattractants especially for neutrophils. C5 can be activated by an abundance of oxygen free radicals. The subsequent generation of the MAC perturbs the maintenance of vital ion gradients, induces cell lysis, and facilitates neutrophil recruitment. In addition it can induce the expression of numerous inflammatory mediators, including cytokines (TNF α , IL-1, IL-8), ROS, prostaglandins, LTs, and cell surface adhesion molecules.³⁰²

Systemic Inflammatory Response Syndrome

The inability of host defenses to control a localized inflammatory process or an unchecked inflammatory response can result in SIRS. A recent consensus conference defined SIRS as the presence of any two of the following physiologic parameters: (1) a temperature greater than 38°C or less than 36°C; (2) leukocytosis (>12,000), leukopenia (<4,000), or more than 10% bands; (3) pulse greater than 90 beats per minute; (4) tachypnea (respiratory rate greater than 20 or PaCO₂ < 32 mm Hg).³⁰³ Infection underlies a significant minority of cases as only a third of patients with SIRS will have a documented infection and meet the criteria for sepsis. There is a continuum from the development of SIRS to sepsis, to severe sepsis, septic shock, and MODS.³⁰⁴ The outcome depends on the balance between SIRS and host compensatory mechanisms. In one prospective study, 26% of patients with SIRS developed sepsis and 7% died.³⁰⁵

SIRS may be initiated by infectious or noninfectious causes, such as trauma, autoimmune reactions, or pancreatitis. Gram-negative organisms, rich in LPS, induce a potent inflammatory response mediated through the CD14/TLR4/MyD88 pathway previously described and account for the majority of infectious SIRS cases. Gram-positive organisms can generate a similarly impressive degree of inflammation either through TLR2 or alternative mechanisms. Streptococcal superantigen may induce a global and nonspecific activation of T cells that culminates in massive systemic elaboration of cytokines and cardiovascular collapse termed TSS. Trauma, either through tissue injury (HMGB1-RAGE, HSP-CD91) or the ischemia/reperfusion consequent to hemorrhage can culminate in inflammatory pathophysiology indistinguishable from that accompanying these other inflammatory states. As the growing evidence continues to support the promiscuity of TLR and other signaling pathways, we are replacing the former concept distinct receptor-signaling mechanisms for each stimulus with one that emphasizes the similarities, overlap and integration. Though there are clearly mechanisms by which host distinguishes normal self from endogenous (trauma) and exogenous (infection) dangers, there is considerable overlap, and all stimuli appear to converge upon similar signaling mechanisms in attaining

the goal of preserving the host.

The development of SIRS has been described as progressing through three stages: Stage I – local cytokine production recruits inflammatory cells to the injured site; Stage II – an acute-phase response is initiated and small quantities of cytokines are released into the circulation to enhance the local response; and Stage III – homeostasis cannot be reestablished.³⁰⁶ Enhanced levels of CRP, the major acute-phase protein in humans, occur in SIRS/sepsis, and clinical resolution is preceded by a drop in CRP levels.

The elaboration of proinflammatory cytokines (IL-1, TNF α , and IL-6) is central to the pathogenesis of SIRS regardless of the initiating stimulus. Their release triggers increased expression of adhesion molecules, leukocyte recruitment, and the production of secondary proinflammatory mediators, such as chemokines. Endotoxin is one of the most powerful triggers of SIRS. LPS activates the complement and coagulation cascades, induces endothelial cell activation, and increases TNF α and IL-1 synthesis, and the late release of HMGB1. However, noninfectious tissue injury induces a similar inflammatory response. LPS, TNF α , and IL-1 also induce increased production of NO by iNOS. PGI₂ and arachidonic acid, together with NO contribute to decreased systemic vascular resistance and hypotension. Autocrine and paracrine NO production also results in myocardial depression. Increased vascular permeability promotes extravasation of fluid and edema formation. Activated endothelial cells express tissue factor, PECAM, and TXA₂, which promote a procoagulant local environment that predisposes to microthrombi formation. Adherent leukocytes further exacerbate organ injury by mechanically impeding microvascular blood flow and by damaging the endothelial cells and surrounding connective tissue. The results are end-organ hypoperfusion, inadequate oxygen delivery, initiation of anaerobic metabolism, and organ failure. The metabolic and nutritional sequelae of this activated cytokine milieu includes fever, catabolism, cachexia, and altered fat, glucose, and trace mineral metabolism.

SIRS is counteracted by the concomitant induction of an anti-inflammatory response termed the compensatory anti-inflammatory response syndrome (CARS).³⁰⁶ Many of the proinflammatory mediators that participate in SIRS modulate the immune function of lymphocytes and mononuclear cells. Proinflammatory mediators can inhibit their own synthesis or enhance the synthesis of natural antagonists by negative feedback mechanisms. Thus, at any given time, the clinical manifestation is SIRS, CARS, or an intermediate, mixed inflammatory response syndrome. The spectrum of features that characterizes these syndromes has been termed CHAOS (cardiovascular shock, homeostasis, apoptosis, organ dysfunction, and immune suppression). Studies employing a variety of specific anticytokine agents have failed to observe an improvement in the outcome of patients with SIRS or sepsis.

Chronic Inflammation

There are no clear boundaries between an acute and a chronic inflammatory response. In general, if the source of an acute inflammatory process is incompletely eliminated, a state of chronic inflammation eventually ensues. Chronicity is usually not characterized by the signs classically associated with acute responses, such as swelling, heat, or redness. Pain is minimal if not absent. Microscopically, a mononuclear cell infiltrate predominates (lymphocytes, monocytes, plasma cells) with proliferation of fibroblasts and vascular elements.

Many agents can create a state of chronic inflammation, including persistent infectious agents, remnants of dead organisms, foreign bodies, and metabolic byproducts. Ultimately, chronicity of inflammation is a result of the immune response to a persistent antigen. Furthermore, a chronic inflammatory response can develop in the absence of a preceding acute response, such as infections with agents of low toxicity such as mycobacterium and treponema. CD4⁺ T cells and macrophages are the primary cellular orchestrators of chronic inflammatory response.³⁰⁷ T_H1 cell-mediated immune responses are protective against most microbes and usually result in the elimination of the pathogen. If the microbe persists, the ongoing T_H1 response results in inflammatory tissue injury. Cytokines and growth factors released by T lymphocytes and macrophages stimulate proliferative responses. Neutrophils and eosinophils contribute to the release of proteolytic enzymes and oxygen derivatives. Eosinophilia occurs with chronic parasitic infections and hypersensitivity conditions. Fibroblasts are actively recruited by chemoattractants such as fibrin, collagens, and cytokines. Local IL-1 stimulates fibroblast proliferation and collagen production. Irreversible tissue damage can occur through the replacement of normal parenchyma with fibrous connective tissue. Fibroblasts can release metalloproteinases that degrade normal tissue, further contributing to tissue destruction. Mast cells are elevated in chronic conditions and may play a part in cell-mediated immune responses. Inflammatory cyst formation may occur as a result of epithelial hyperplasia.

Chapter 8

Surgical Infections

Lena M. Napolitano

Key Points

- 1 Surgical infections include intra-abdominal infections (appendicitis, cholecystitis/cholangitis, diverticulitis, colitis including *C. difficile* colitis, pancreatitis, and peritonitis), soft tissue infections (necrotizing and nonnecrotizing), surgical site infections, and hospital-acquired infections that occur in surgical patients (pneumonia, central line-associated bloodstream infections [CLABSI], and catheter-associated urinary tract infections [CAUTI]).
 - 2 Early empiric appropriate broad-spectrum antimicrobial therapy, to cover all potential causative pathogens, is an important adjunct to source control in the treatment of surgical infections. Inappropriate antimicrobial therapy is associated with increased mortality.
 - 3 Any of these surgical infections can result in severe sepsis or septic shock.
 - 4 A key concept in surgical infections is “*source control*,” defined as any physical intervention to remove or eliminate a focus of invasive infection (drainage, debridement, and device removal) and to restore optimal anatomic function.
 - 5 Pathogen identification and appropriate deescalation of antimicrobial therapy are of paramount importance in treatment of surgical infections, as increasing prevalence of multidrug-resistant pathogens has been identified in both abdominal and skin surgical infections.
 - 6 Complicated intra-abdominal infection (cIAI) extends beyond the hollow viscus of origin into the peritoneal space and is associated with either abscess formation or peritonitis.
 - 7 Recommendations for specific antimicrobial therapy for cIAI are based on whether the infection is “community-acquired” or “healthcare-associated.”
 - 8 In patients with intra-abdominal infections who have undergone an adequate source control procedure, fixed-duration antibiotic therapy for 4 days is noninferior to longer duration antimicrobial therapy until resolution of physiologic abnormalities, with no difference in surgical site infection, recurrent intra-abdominal infection, or death.
 - 9 The two surgical procedures indicated for *C. difficile* colitis treatment include (1) total abdominal colectomy (for peritonitis, colonic perforation, ischemia, necrosis, toxic megacolon with impending perforation, septic shock with organ failure) and (2) diverting loop ileostomy and intraoperative colonic lavage for toxin reduction. The second option is associated with colonic preservation.
 - 10 The initial treatment of infected pancreatic necrosis is percutaneous catheter or endoscopic (transgastric/transduodenal) drainage with additional drain placement as required.
 - 11 Lack of clinical improvement of necrotizing infected pancreatitis with initial percutaneous drainage warrants consideration of minimally invasive techniques for pancreatic necrosectomy including video-assisted retroperitoneal debridement, minimally invasive retroperitoneal pancreatectomy, or transluminal direct endoscopic necrosectomy.
 - 12 Acute bacterial skin and skin structure infections are defined as bacterial infection of the skin with a lesion size area of at least 75 cm² (lesion size measured by the area of redness, edema, or induration), including cellulitis, wound infection, and abscess.
 - 13 Early operative debridement is the major determinant of outcome in necrotizing soft tissue infections. Delayed definitive debridement remains the single most important risk factor for death.
-

INTRODUCTION

1 Surgical infections include intra-abdominal infections (appendicitis, cholecystitis, diverticulitis, colitis, and pancreatitis), soft tissue infections (necrotizing and nonnecrotizing), surgical site infections (SSIs),

and hospital-acquired infections that occur in surgical patients (pneumonia, central line–associated bloodstream infections [CLABSI], and catheter-associated urinary tract infections [CAUTI]).¹ Appropriate therapy of surgical infections to optimize patient outcomes includes four steps: (1) early diagnosis, (2) early initiation of appropriate empiric broad-spectrum antimicrobial therapy, (3) adequate source control (surgical or interventional radiologic), and (4) pathogen identification and appropriate deescalation of antimicrobial therapy (Table 8-1).

The initial management of all surgical infections should include the initiation of early empiric antimicrobial therapy to cover all potential possible pathogens, since early and appropriate empiric antibiotic therapy improves patient outcomes (Table 8-2).² The choice of early empiric antimicrobial therapy is guided by the specific site of infection, the common pathogens associated with that infection, and by local and regional antibiograms. The goal of antimicrobial therapy is to achieve antibiotic levels at the site of the infection that exceed the minimum inhibitory concentration of the microbial pathogens present.

Early Use of Appropriate Broad-Spectrum Antimicrobial Therapy

2, 3 Early use of appropriate broad-spectrum antimicrobial therapy is an important adjunct to appropriate surgical management of surgical infections. Numerous studies have confirmed that inappropriate empiric antibiotics (i.e., antibiotics that do not cover the causative pathogens) are associated with increased mortality.³ In patients who manifest severe sepsis or septic shock, every hour delay of antimicrobial therapy is associated with increased mortality.⁴ The Surviving Sepsis Guidelines recommendations are listed in Table 8-3.

Table 8-1 Appropriate Therapy of Surgical Infections

1. Early diagnosis of surgical infection
 2. Early initiation of appropriate empiric broad-spectrum antimicrobial therapy
 3. Adequate source control
 4. Pathogen identification and appropriate deescalation of antimicrobial therapy

Source Control

4 Source control is defined as any physical intervention to remove or eliminate a focus of invasive infection (drainage, debridement, and device removal) and to restore optimal anatomic function.⁵ In surgical infections, antimicrobial agents are used in conjunction with adequate source control of the initial infection. Adequate source control can be accomplished by either surgical or percutaneous interventional radiologic techniques. A number of factors have been identified that predict failure of source control for intra-abdominal infections (Table 8-4).

Pathogen Identification

5 Pathogen identification is extremely important, in part related to increased prevalence of multidrug-resistant pathogens that are associated with surgical infections. Whenever possible, high-quality specimens should be obtained from source control procedures for Gram stain and culture in order to identify causative pathogens and determine antimicrobial susceptibility of the bacterial isolates identified. This will enable appropriate deescalation of antimicrobial therapy from broad-spectrum therapy to directed potential single antimicrobial agent therapy.

INTRA-ABDOMINAL INFECTIONS

Classification

6 Complicated intra-abdominal infection (cIAI) extends beyond the hollow viscus of origin into the peritoneal space and is associated with either abscess formation or peritonitis. “Uncomplicated” intra-abdominal infection involves intramural inflammation of the gastrointestinal tract and has a substantial probability of progressing to cIAI if not adequately treated.

Table 8-2 Spectrum of Activity of Specific Antimicrobials for Specific Pathogens

Antibiotic	Gram-Negative	Gram-Positive	Resistant Gram-Negative	Resistant Gram-Positive	Anaerobe	Pseudomonas
Beta-lactam/beta-lactamase inhibitor	+	+	#	0	+	#
First-generation cephalosporins	0	+	0	0	0	0
Second-generation cephalosporins	#	#	0	0	0	0
Third-generation cephalosporins	+	+	#	0	0	#
Fourth-generation cephalosporins	+	+	#	0	0	#
Fifth-generation cephalosporins	0	+	0	+	0	0
Tigecycline	+	+	+	+	+	0
Glycopeptides	0	+	0	+	0	0
Carbapenems	+	+	#	0	+	#
Quinolones	+	+	0	0	#	#

0, no activity; +, activity; #, activity, but varies by product within class.

Table 8-3 Antimicrobial Therapy, Surviving Sepsis Guidelines 2012

1. Administration of effective intravenous antimicrobials within the first hour of recognition of septic shock (grade 1B) and severe sepsis without septic shock (grade 1C) as the goal of therapy.
- 2a. Initial empiric anti-infective therapy of one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis (grade 1B).
- 2b. Antimicrobial regimen should be reassessed daily for potential deescalation (grade 1B).
3. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empiric antibiotics in patients who initially appeared septic, but have no subsequent evidence of infection (grade 2C).

Diagnosis

Patients with cIAI present with abdominal pain and gastrointestinal symptoms. A comprehensive abdominal physical examination must be performed in these patients. If peritonitis is present, evaluation for emergent laparotomy without diagnostic studies is considered. If peritonitis is not present, recent evidence-based guidelines recommend that computed tomography (CT) scan of the abdomen and pelvis is the diagnostic imaging modality of choice to evaluate for cIAI and its source.^{6,7}

Treatment

7 Early empiric appropriate systemic antimicrobial therapy to cover all potential causative pathogens and early source control are the mainstays of treatment of cIAIs. In order to select appropriate empiric antimicrobial agents for use, cIAIs are further classified as “community-acquired” or “healthcare-associated.”

Community-Acquired Complicated Intra-Abdominal Infection

For patients who have “community-acquired” cIAI, determination of whether the disease is “mild/moderate (appendicitis, mild diverticulitis)” or “severe (fecal peritonitis, perforated diverticulitis)” facilitates appropriate antimicrobial treatment (Table 8-5). Patients with “severe” community-acquired cIAI should have antibiotics that cover *Pseudomonas* and *Enterococcus* pathogens, and both single-agent and combination-agent regimens are available for use. A number of antimicrobials are no longer recommended for use in community-acquired cIAI:

Table 8-4 Clinical Factors Predicting Failure of “Source Control” for Intra-Abdominal Infection

Delay in the initial intervention (>24 h)
High severity of illness (APACHE [Acute Physiology and Chronic Health Evaluation] II score ≥15)
Advanced age
Comorbidity and degree of organ dysfunction
Low albumin level
Poor nutritional status
Degree of peritoneal involvement or diffuse peritonitis
Inability to achieve adequate drainage or debridement
Presence of malignancy

- Ampicillin/sulbactam is not recommended because of high resistance of *Escherichia coli* to this agent (B-II)
- Cefotetan and clindamycin are not recommended for use because of increasing resistance of the *Bacteroides fragilis* group to these agents (B-II)
- Because of the availability of less toxic agents demonstrated to be of at least equal efficacy, aminoglycosides are not recommended for routine use in community-acquired IAI in adults (B-II).

Healthcare-Associated Complicated Intra-Abdominal Infection

For patients with “healthcare-associated” cIAI, separate evidence-based guideline recommendations for empiric antimicrobial treatment are provided ([Algorithm 8-1](#)). Specific antimicrobials are recommended based on whether the patient and/or institution have high risk for infection with multidrug-resistant pathogens. Quinolone-resistant *E. coli* have become common in many communities, and quinolones should not be used unless hospital antibiograms confirm greater than 90% susceptibility of *E. coli* to quinolones. In patients with healthcare-associated cIAI, carbapenems are an excellent single-agent regimen for empiric treatment.

Table 8-5 Empiric Antimicrobial Treatment of Extrabiliary cIAIs, Community Acquired

	Community-Acquired Infections in Adults	
	Mild to Moderate	Severe
Single agent	■ Cefoxitin ■ Ertapenem ■ Moxifloxacin ■ Tigecycline ■ Ticarcillin/clavulanic acid	■ Imipenem/cilastatin ■ Meropenem ■ Doripenem ■ Piperacillin/tazobactam
Combination regimen	■ Cefazolin,^a cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levofloxacin, each in combination with metronidazole	■ Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole

■ Ampicillin/sulbactam is not recommended because of high resistance of *Escherichia coli* to this agent (B-II).
 ■ Cefotetan and clindamycin are not recommended for use because of increasing resistance of the *Bacteroides fragilis* group to these agents (B-II).
 ■ Because of the availability of less toxic agents demonstrated to be of at least equal efficacy, aminoglycosides are not recommended for routine use in community-acquired IAI in adults (B-II).

^aCaution – local antibiograms should direct use of this agent.
 Adapted from Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11(1):79–109.

Duration of Antibiotics for Complicated Intra-Abdominal Infection

8 Duration of antibiotics for treatment of cIAI has long been controversial. A recent important randomized controlled trial examined the efficacy of short-course (4 days) antimicrobial therapy in patients with intra-abdominal infections who had undergone an adequate source control procedure. Fixed-duration antibiotic therapy for 4 days was noninferior to longer duration antimicrobial therapy until resolution of physiologic abnormalities, with no difference in the composite endpoints of SSI, recurrent intra-abdominal infection, or death.⁸

SPECIFIC INTRA-ABDOMINAL INFECTIONS

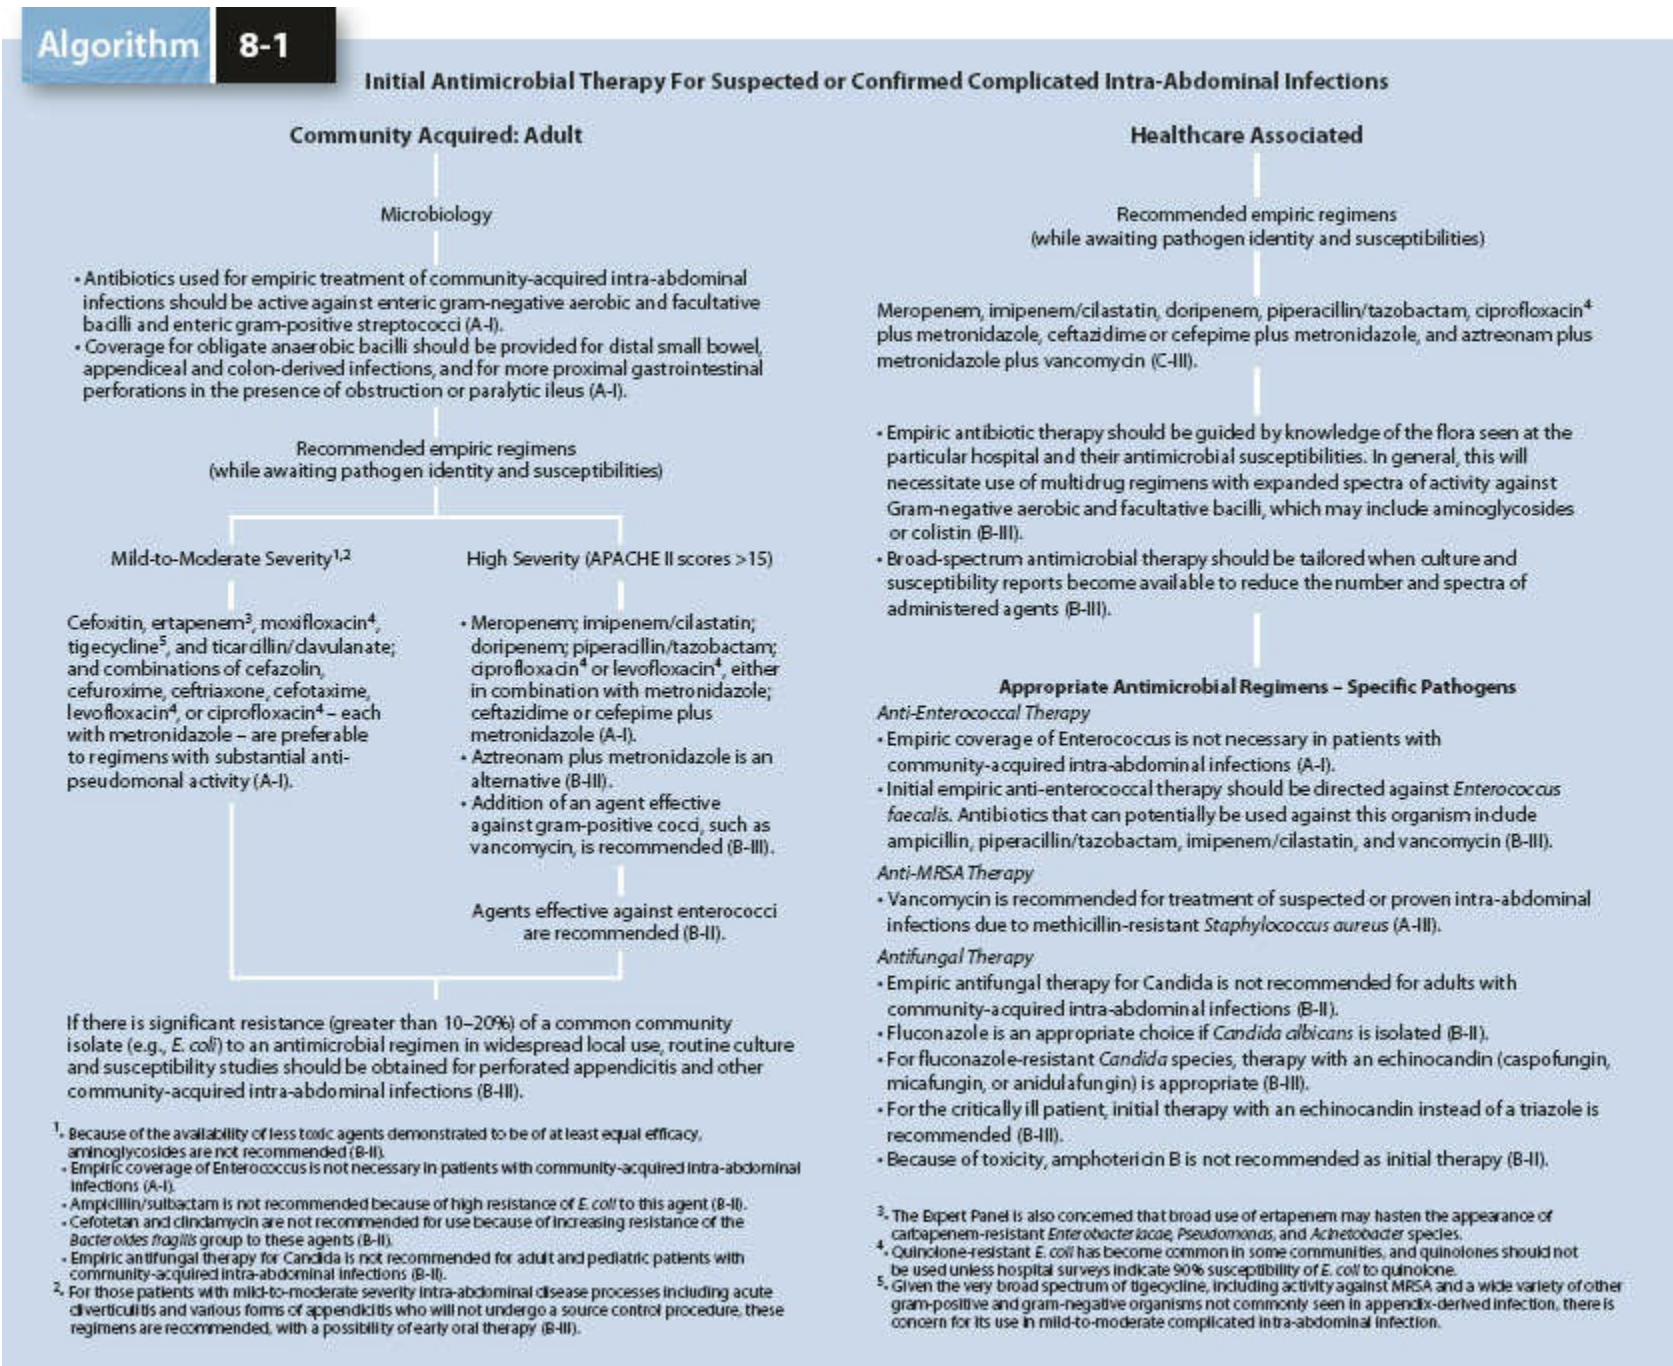

Appendicitis

Appendicitis is common with over 300,000 hospital discharges in the United States per year. Although appendectomy provides definitive source control for the treatment of acute nonperforated appendicitis,

intravenous (IV) antibiotics should be administered preoperatively with a dose repeated intraoperatively if the surgery is prolonged, a number of controversies in diagnosis and management of appendicitis persist.⁹

Antibiotics versus Appendectomy

In patients with uncomplicated appendicitis (nonperforated, no abscess, or phlegmon), appendectomy is definitive source control. But a number of recent randomized trials have confirmed that acute nonperforated appendicitis can be treated successfully with antibiotics alone. A meta-analysis of 6 studies with 1,201 patients reported that in patients treated with antibiotics alone, $7 \pm 4\%$ failed to respond and required appendectomy, and acute appendicitis recurred in $14 \pm 11\%$. A normal appendix was found in $7.3 \pm 5.1\%$ of patients at appendectomy. Complications were considerably less likely to occur with antibiotic treatment than with appendectomy. Major surgical complications included enterocutaneous fistula and reoperation.¹⁰

Healthcare Associated

Recommended empiric regimens (while awaiting pathogen identity and susceptibilities)

Meropenem, imipenem/cilastatin, doripenem, piperacillin/tazobactam, ciprofloxacin⁴ plus metronidazole, ceftazidime or ceftipime plus metronidazole, and aztreonam plus metronidazole plus vancomycin (C-III).

- Empiric antibiotic therapy should be guided by knowledge of the flora seen at the particular hospital and their antimicrobial susceptibilities. In general, this will necessitate use of multidrug regimens with expanded spectra of activity against Gram-negative aerobic and facultative bacilli, which may include aminoglycosides or colistin (B-III).
- Broad-spectrum antimicrobial therapy should be tailored when culture and susceptibility reports become available to reduce the number and spectra of administered agents (B-III).

Appropriate Antimicrobial Regimens – Specific Pathogens

Anti-Enterococcal Therapy

- Empiric coverage of *Enterococcus* is not necessary in patients with community-acquired intra-abdominal infections (A-I).
- Initial empiric anti-enterococcal therapy should be directed against *Enterococcus faecalis*. Antibiotics that can potentially be used against this organism include ampicillin, piperacillin/tazobactam, imipenem/cilastatin, and vancomycin (B-III).

Anti-MRSA Therapy

- Vancomycin is recommended for treatment of suspected or proven intra-abdominal infections due to methicillin-resistant *Staphylococcus aureus* (A-III).

Antifungal Therapy

- Empiric antifungal therapy for *Candida* is not recommended for adults with community-acquired intra-abdominal infections (B-II).
- Fluconazole is an appropriate choice if *Candida albicans* is isolated (B-II).
- For fluconazole-resistant *Candida* species, therapy with an echinocandin (caspofungin, micafungin, or anidulafungin) is appropriate (B-III).
- For the critically ill patient, initial therapy with an echinocandin instead of a triazole is recommended (B-III).
- Because of toxicity, amphotericin B is not recommended as initial therapy (B-II).

³ The Expert Panel is also concerned that broad use of ertapenem may hasten the appearance of carbapenem-resistant *Enterobacteriaceae*, *Pseudomonas*, and *Acinetobacter* species.

⁴ Quinolone-resistant *E. coli* has become common in some communities, and quinolones should not be used unless hospital surveys indicate 90% susceptibility of *E. coli* to quinolone.

⁵ Given the very broad spectrum of tigecycline, including activity against MRSA and a wide variety of other gram-positive and gram-negative organisms not commonly seen in appendix-derived infection, there is concern for its use in mild-to-moderate complicated intra-abdominal infection.

Algorithm 8-1. Empiric antimicrobial treatment of extrabiliary cIAs, community acquired versus healthcare associated. (Adapted from Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11(1):79–109.)

A Cochrane meta-analysis of 5 trials with 901 patients reported that 73.4% of patients who were treated with antibiotics and 97.4% patients underwent appendectomy were cured within 2 weeks without major complications (including recurrence) within 1 year.¹¹ Another meta-analysis included only four trials and reported that efficacy was significantly higher for surgery but rates of perforated appendicitis were not different, and complication rates were significantly higher for surgery.¹²

The most recent trial (APPAC) enrolled 530 patients in Finland with uncomplicated appendicitis confirmed by CT scan and randomized to early appendectomy or antibiotic treatment (ertapenem for 3 days, then oral levofloxacin and metronidazole for 7 days) with 1-year follow-up. In the antibiotic group, 70 patients (27.3%) underwent appendectomy within 1 year of initial presentation for appendicitis. Antibiotic treatment did not meet the prespecified criterion for noninferiority compared

with appendectomy. But it was notable that 72.7% of patients with uncomplicated appendicitis treated with antibiotics alone did not require subsequent appendectomy.^{13,14}

The trials published to date were primarily from European countries, used antibiotics not available in the United States and had minimal use of laparoscopic appendectomy or CT scan for diagnostic imaging.¹⁵ Further high-quality randomized trials are therefore needed to determine which patients are most likely to benefit from antibiotic therapy alone. Although appendectomy remains the standard treatment for acute appendicitis, antibiotic treatment alone may be used as an alternative treatment in patients with contraindication to surgery (or where surgery is high risk).

Laparoscopic versus Open Appendectomy

Appendectomy can be performed by laparoscopic or open approach. A large retrospective review (2005–2008) of laparoscopic versus open appendectomy using the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) reported that 76.4% were performed laparoscopically and 23.6% performed open. Open appendectomy was associated with increased morbidity, SSI, and mortality.¹⁶

A Cochrane review of 67 trials was updated in 2010 and reported that laparoscopic appendectomy was associated with lower SSI rates but higher intra-abdominal abscess rate. Laparoscopic approach was associated with shorter hospital length of stay, faster return to normal activity, and decreased postoperative pain. This review concluded that laparoscopic appendectomy should be considered the preferred approach where surgical expertise and equipment are available.¹⁷

Time to Appendectomy and Perforation Risk

It has long been thought that appendiceal luminal obstruction leads to appendiceal perforation without timely surgical intervention. This belief led to attempts to decrease time from presentation and diagnosis of acute appendicitis to operating room start time. With the advent of early appropriate empiric systemic antimicrobial therapy, this fundamental concept is no longer true. As discussed previously, in patients with uncomplicated appendicitis, antibiotic treatment alone does not lead to appendiceal perforation. Furthermore, using data from the Washington State Surgical Care and Outcomes Assessment Program (SCOAP) with 9,048 adult patients who underwent appendectomy, there was no association between appendiceal perforation and in-hospital time prior to surgery. This study confirmed that appendiceal perforation is most commonly a prehospital occurrence, and timing of surgery should be determined based on all factors relevant to the surgeon and patient.¹⁸

Abscess or Phlegmon Management

In patients with periappendiceal abscess or phlegmon, current evidence (mainly retrospective studies) supports nonoperative management with IV transitioned to oral antibiotics and percutaneous drainage if possible. A meta-analysis of 19 retrospective studies from 1969 to 2005 reported that nonsurgical treatment failed in only 7.6% of patients and immediate appendectomy was associated with higher morbidity. Similar findings were confirmed in a more recent review.¹⁹ Routine interval appendectomy is not recommended since the risk of recurrence is low (7.4%). But either colonoscopy or repeat CT imaging is recommended due to the risk of a malignant disease (1.2%) or important benign disease (0.7%) identified during follow-up.²⁰

Algorithm 8-2. Biliary infections and algorithm for diagnosis and management. (From Demehri FR, Alam HB. Evidence-based management of common gallstone-related emergencies. *J Intensive Care Med* 2016;31(1):3–13.)

Interval Appendectomy after Initial Nonoperative Management

A large retrospective cohort study reported that 3% of patients were initially treated with nonoperative management. Of these, 15% had an interval appendectomy and the remaining 85% did not. Of the 864 patients that did not undergo interval appendectomy only 39 patients (5%) had recurrence of appendicitis after a median follow-up of 4 years.²¹ Routine interval appendectomy after initial successful nonoperative treatment is therefore not justified and should be abandoned. In a meta-analysis including 2,771 patients initially treated nonoperatively for appendiceal phlegmon or abscess, 31 patients were found to have a malignant diagnosis and a lower rate of inflammatory bowel disease. These data highlight the need for follow-up with either CT scan or colonoscopy after successful nonoperative management.²⁰ Although a retrospective study in pediatric appendicitis reported a 2.8-fold higher rate of recurrent appendicitis in patients with an appendicolith, this study is limited by small sample size ($n = 96$) and a higher overall rate of recurrent appendicitis than all other published studies.²² See also chapter on Appendiceal Diseases.

Biliary Infections

Biliary infections include acute cholecystitis which may be calculous or acalculous, may include choledocholithiasis or not, and cholangitis.²³ Acute cholecystitis and ascending cholangitis are primary inflammations of the gallbladder and bile ducts, respectively, which are caused by infection and possible biliary obstruction.

Acute Cholecystitis

Acute cholecystitis is inflammation of the gallbladder resulting from obstruction of the cystic duct and subsequent bacterial invasion and overgrowth. Cholelithiasis is the cause of cystic duct obstruction in more than 90% of cases of acute cholecystitis in the United States. Acalculous cholecystitis is more common in critically ill patients and the pathophysiology is transmural ischemia. Acalculous cholecystitis carries higher morbidity and mortality rates than calculous cholecystitis.

The diagnosis of acute cholecystitis is made based on the common constellation of right upper quadrant tenderness, leukocytosis, and fever. Initial diagnostic imaging is right upper quadrant ultrasound to evaluate for gallstones, gallbladder wall thickening, and pericholecystic inflammation (sensitivity 88% to 94%, specificity 78% to 80%). If ultrasound is inconclusive or is discordant with the

clinical evaluation, then cholescintigraphy (99mTc-hepatobiliary iminodiacetic acid, HIDA scan) is recommended and nonvisualization of the gallbladder confirms acute cholecystitis with sensitivity of 96% and specificity of 90% (Algorithm 8-2).²⁴

Early systemic antimicrobial treatment is indicated for acute cholecystitis to cover the causative pathogens, including aerobic, enteric, gram-negative bacilli (i.e., *E. coli*, *Klebsiella*, *Enterobacter*, and *Proteus*), and aerobic gram-positive organisms (i.e., *Enterococcus* and *Streptococcus*). Anaerobes are uncommon, identified in approximately 15% of isolates. Clostridial organisms can be identified in cases of emphysematous cholecystitis confirmed by identification of gas in the gallbladder wall.

Cholangitis

Cholangitis signs/symptoms include jaundice, fever, right upper quadrant tenderness, hyperbilirubinemia, and leukocytosis. Ultrasound confirms common bile duct dilation (>7 mm).

Appropriate evidence-based recommendations for diagnosis and treatment from the Tokyo Guidelines are provided in Tables 8-6 and 8-7. For treatment recommendations, urgent biliary drainage (<24 hours) is indicated when (1) obstructive biliary stones are associated with severe or moderate acute cholangitis OR (2) mild acute cholangitis is not responding to IV antibiotics and fluid resuscitation.

For patients with biliary infections, specific evidence-based guideline recommendations for antimicrobial treatment are classified into four patient populations (Table 8-8). For patients undergoing cholecystectomy for acute cholecystitis with complete source control (i.e., complete cholecystectomy), antimicrobial therapy should be discontinued within 24 hours of the operation unless there is evidence of infection outside the wall of the gallbladder. See also chapter on Calculous Biliary Disease.

Table 8-6 Diagnosis of Cholangitis: Tokyo Guidelines 2013

Systemic inflammation	■ Fever and/or shaking chills laboratory data: evidence of inflammatory response (WBC, CRP, etc.)
Cholestasis	■ Jaundice (total bilirubin ≥2 mg/dL) ■ Laboratory data: abnormal liver function tests (ALP, GGT, AST, and ALT)
Imaging	■ Biliary dilatation ■ Evidence of the etiology on imaging (stricture, stone, stent, etc.) ■ Clinical gallstone pancreatitis
Diagnosis of cholangitis	Suspected: presence of 1 item in A + 1 item in either B or C Definite: presence of 1 item in A, 1 item in B, and 1 item in C

ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate aminotransferase/aspartate transaminase; CRP, C-reactive protein; GGT, γ-glutamyl transferase; WBC, white blood cell.
Adapted from Kiriya S, Takada T, Strasberg SM, et al. TG13 guidelines for diagnosis and severity grading of acute cholangitis (with videos). *J Hepatobiliary Pancreat Sci* 2013;20(1):24–34.

Table 8-7 Treatment of Acute Cholangitis by Severity Classification: Tokyo Guidelines 2013 Criteria

Severity of Acute Cholangitis	
Mild (grade I)	Does not meet the criteria of “severe” or “moderate” acute cholangitis at time of initial diagnosis
Moderate (grade II)	Acute cholangitis associated with any two of the following conditions: ■ Abnormal WBC ($>12,000$, $<4,000/\text{mm}^3$) ■ High fever ($\geq 39^\circ\text{C}$) ■ Age ≥ 75 years old ■ Hyperbilirubinemia (total bilirubin ≥ 5 mg/dL) ■ Hypoalbuminemia ($<$lower limit of normal $\times 0.7$)
Severe (grade III)	Acute cholangitis associated with the onset of dysfunction in at least one of the following organs/systems: ■ Cardiovascular dysfunction (hypotension requiring pressors) ■ Neurologic dysfunction (disturbance of consciousness) ■ Respiratory dysfunction ($\text{PaO}_2/\text{FiO}_2$ ratio <300) ■ Renal dysfunction (oliguria, serum creatinine >2 mg/dL) ■ Hepatic dysfunction (elevated PT/INR >1.5) ■ Hematologic dysfunction (platelet count $<100,000/\text{mm}^3$)
Assessment of Urgency of Draining Urgent biliary drainage (<24 h) is indicated when a. Obstructive biliary stones are associated with severe or moderate acute cholangitis OR b. Mild acute cholangitis is not responding to IV antibiotics and fluid resuscitation Early (but not urgent) ERCP (<72 h) is recommended for patients with mild acute cholangitis who respond to medical therapy	

ERCP, endoscopic retrograde cholangiopancreatography; PT/INR, prothrombin time and international normalized ratio.
Adapted from Kiriya S, Takada T, Strasberg SM, et al. TG13 guidelines for diagnosis and severity grading of acute cholangitis (with videos). *J Hepatobiliary Pancreat Sci* 2013;20(1):24–34.

Diverticulitis

Diverticulitis is a common intra-abdominal infection. Its pathophysiology is associated with altered gut motility, increased luminal pressure, and an altered colonic microenvironment.

Uncomplicated diverticulitis is treated with systemic antibiotics and usually resolves. Antimicrobial treatment of diverticulitis is the same as for cIAI which is reviewed above. In a cohort study of 2,366 patients hospitalized in the Kaiser Permanente system and followed for 8.9 years, only 13.3% had a first recurrence and 3.9% had a second recurrence.²⁵

Surgery for acute diverticulitis is indicated for patients who present with peritonitis and/or sepsis or who do not improve with medical management and/or percutaneous drainage of associated abscess/infection. Although less than 25% of patients will develop generalized peritonitis after colonic perforation, it is severe with high mortality. Surgical options include simple colostomy formation in the setting of profound inflammation (rarely performed), traditional sigmoid resection with colostomy (Hartmann procedure), and sigmoid resection with a primary colocolonic or colorectal anastomosis with or without a diverting loop ileostomy. Laparoscopic surgery is preferred to open surgery when possible.²⁶

Table 8-8 Antimicrobials for Treatment of Biliary Infections

Community-acquired acute cholecystitis of mild to moderate severity
■ Cefazolin
■ Cefuroxime
■ Ceftriaxone
Community-acquired acute cholecystitis of severe physiologic disturbance, advanced age, or immunocompromised state
■ Imipenem/cilastatin
■ Meropenem
■ Doripenem
■ Piperacillin/tazobactam
■ Ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole
Acute cholangitis following bilioenteric anastomosis of any severity
■ Imipenem/cilastatin
■ Meropenem
■ Doripenem
■ Piperacillin/tazobactam
■ Ciprofloxacin, levofloxacin, or cefepime each in combination with metronidazole
Healthcare-associated biliary infection of any severity
■ Imipenem/cilastatin
■ Meropenem
■ Doripenem
■ Piperacillin/tazobactam
■ Ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole
■ Vancomycin added to each regimen

Adapted from Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11(1):79–109.

Figure 8-1. Hinchey classification scheme. Patients with stage 1 disease have small, confined, pericolic, or mesenteric abscesses, whereas those with stage 2 disease have larger abscesses, often confined to the pelvis. Stage 3 disease, or perforated diverticulitis, is present when a peridiverticular abscess has ruptured and caused purulent peritonitis. Rupture of an uninflamed and unobstructed diverticulum into the free peritoneal cavity with fecal contamination, the so-called free rupture, signifies stage 4 disease and carries the highest risk of an adverse outcome.

Since recurrence after recovery from an uncomplicated episodes of diverticulitis is rare and two or more recurrences are not associated with increased risk of complications, elective colectomy following two episodes of diverticulitis is no longer recommended. Decisions regarding surgical intervention and colectomy must therefore be based on individual potential risks and benefits of colon resection.²⁷

For patients who require surgical intervention, the specific treatment that is associated with the best outcome is controversial. Hinchey proposed a practical clinical classification of diverticulitis based on the severity of peritoneal contamination (Fig. 8-1) identified at operation.²⁸ The modified Hinchey classification includes Hinchey Ia (confined pericolic inflammation–phlegmon) and Ib (confined pericolic

abscess) and considers classification based on radiologic imaging with CT scan as well. Increasing Hinchey classification is associated with increased mortality. The mortality for patients with Hinchey III is reported as 6% but increases greatly to 35% for fecal peritonitis (Hinchey IV). A systematic review comparing surgical treatments for Hinchey III or IV colonic diverticulitis confirmed that primary resection with anastomosis has a significant advantage with lower mortality compared to Hartmann procedure. Furthermore, laparoscopic peritoneal lavage with subsequent surgical resection if indicated had lower surgical morbidity and hospital length of stay compared to the primary resection and anastomosis group.²⁹ See also chapter on Diverticular Disease.

Figure 8-2. Treatment of initial episode of *Clostridium difficile* infection.

Clostridium Difficile Colitis

The incidence and severity of *Clostridium difficile* infection (CDI) has increased, particularly in surgical patients who have been exposed to prior antimicrobial therapy. There has been a substantial change in the management of CDI related to the emergence of the NAP1/BI/027 strain which is associated with higher toxin production and more severe forms of disease. CDI may be associated with mild to moderate diarrhea or colonic ileus and obstipation to severe colitis.³⁰

Early diagnosis of CDI is imperative. Recommended testing includes two steps, using a glutamine dehydrogenase assay for the *Clostridium difficile* antigen, followed by enzyme immunoassay toxin testing. Polymerase chain reaction (PCR) confirmatory testing is used if the antigen is positive and toxin is negative.³¹ Radiologic testing is helpful, and CT may show colonic mucosal edema (thumbprinting or target sign), ascites, inflammation, and fat stranding and the “accordion sign” which indicates alternating edematous colonic haustra separated by transverse mucosal ridges filled with enteral contrast.

Initial management of CDI is cessation of all antibiotics if possible. The 2010 SHEA/IDSA guidelines have evidence-based recommendations for CDI based on severity of disease (Fig. 8-2).³² Vancomycin and metronidazole are first-line therapy. Vancomycin is preferred for severe or complicated disease. Fidaxomicin (a macrocyclic antibiotic with a narrow antimicrobial spectrum against *C. difficile*, staphylococci, and enterococci) may be considered for recurrent CDI or where risk of recurrence is high. A multicenter multinational randomized trial confirmed decreased recurrence rates compared to oral vancomycin and it is the U.S. Food and Drug Administration (FDA) approved with a recommended treatment dose of 100 mg po bid.³³ Fecal microbiota transplantation is associated with symptom resolution and may be effective in recurrent CDI, but has no role in primary CDI treatment.

9 CDI may warrant surgical intervention. Surgical consultation should occur very early in the course

of disease in patients with severe and complicated CDI. The indications for surgical management of CDI patients are not clearly defined, but severe disease, worsening clinical condition despite appropriate treatment, and peritonitis or shock states are all potential indications. The two surgical procedures indicated for CDI treatment include (1) total abdominal colectomy (for peritonitis, colonic perforation, ischemia, necrosis, toxic megacolon with impending perforation, septic shock with organ failure) and (2) diverting loop ileostomy and intraoperative colonic lavage for toxin reduction while preserving the colon (Fig. 8-3). This new treatment strategy resulted in reduced mortality compared with the historical population who had undergone total abdominal colectomy (19% vs. 50%), and preservation of the colon was achieved in 93% of patients.³⁴ No randomized studies have been published to date comparing these two options.

Pancreatitis

A new classification of acute pancreatitis has been implemented and is based on local disease (whether pancreatic necrosis is present or not, whether it is sterile or infected) and systemic determinants (whether organ failure is present or not, whether it is transient or persistent) of severity (Table 8-9). Early management requires goal-directed fluid resuscitation (with avoidance of over-resuscitation and abdominal compartment syndrome), assessment of severity of pancreatitis, diagnostic CT imaging to assess for necrotizing pancreatitis, consideration of endoscopic retrograde cholangiopancreatography (ERCP) for biliary pancreatitis, and early enteral nutrition support. Antibiotic prophylaxis for severe acute or necrotizing pancreatitis is not recommended.³⁵

Figure 8-3. Diverting loop ileostomy with antegrade colonic irrigation for CDI. Before surgery is started:

1. Place the patient in lithotomy position with easy access to rectum
2. Place a fluid collection bag (commonly used by urology) under the patient’s rectum for drainage collection
3. Place a rectal drainage tube (large Malecot catheter, large foley catheter, #9 or #10 endotracheal tube, or other large catheter)
4. Have 8 L of warmed polyethylene glycol 3350/electrolyte solution (GoLytely; Braintree Laboratories) available in OR for intraoperative colonic irrigation, and dulcolax suppository

Intraoperatively:

1. Ensure that the colon is viable and without perforation
2. Create a loop ileostomy (laparoscopic or open)
3. Place a 24-French Malecot catheter into the efferent limb of the ileostomy and advance into the right colon through the ileocecal valve. Secure to skin with sutures.
4. Infuse 8 L of warmed polyethylene glycol 3350/electrolyte solution (GoLytely; Braintree Laboratories) into the 24-French Malecot catheter via the efferent limb of the ileostomy
5. Once colonic lavage completed, perform rectal examination to empty rectum, place dulcolax suppository in rectum to encourage colonic emptying
6. Instill antegrade colonic enema with vancomycin (500 mg in 500 mL) via ileostomy efferent limb, continue postoperatively

(Adapted from Neal MD, Alverdy JC, Hall DE, et al. Diverting loop ileostomy and colonic lavage. An alternative to total abdominal colectomy for the treatment of severe, complicated clostridium difficile-associated disease. *Ann Surg* 2011;254(3):423–429.)

Table 8-9 New International Classification of Acute Pancreatitis: Determinants of Severity of Acute Pancreatitis by the 2011 World Congress of the International Association of Pancreatology

Mild AP	No evidence of necrosis or organ failure		
Moderate AP	Evidence of sterile necrosis or transient organ failure		
Severe AP	Evidence of infected necrosis or persistent organ failure		
Critical AP	Evidence of infected necrosis and persistent organ failure		
Local Determinant: Peri/Pancreatic Necrosis	Systemic Determinant: Organ Failure		
Nonviable tissue located in the pancreas alone, or in the pancreas and peripancreatic tissues, or in peripancreatic tissues alone. It can be solid or semisolid (partially liquefied) and is without a radiologically defined wall	Defined for three organ systems on the basis of the worst measurement over a 24-h period. In patients without pre-existing organ dysfunction, defined as either SOFA score of 2 or more in the assessed organ system are: ■ Cardiovascular: need for inotropic agent ■ Renal: $\geq 171 \mu\text{mol/L}$ ($\geq 2 \text{ mg/dL}$) ■ Respiratory: $\text{PaO}_2 \leq 30 \text{ mm Hg}$ ($\leq 40 \text{ kPa}$)		
Sterile necrosis	No proven infection in necrosis	Transient organ failure	Evidence of organ failure in the same organ system for less than 48 h.
Infected necrosis	At least one is present: 1. Gas bubbles within peri/pancreatic necrosis on CT 2. Positive culture by image-guided fine-needle aspiration 3. Positive culture obtained during the first drainage and/or necrosectomy	Persistent organ failure	Evidence of organ failure in the same organ system for 48 h or more.

SOFA, sepsis-related organ failure assessment score; CT, computed tomography.

Adapted from Dellinger EP, Forsmark CE, Layer P, et al.; Pancreatitis Across Nations Clinical Research and Education Alliance (PANCREA).

Determinant-based classification of acute pancreatitis severity: an international multidisciplinary consultation. *Ann Surg* 2012;256:875–880.

Necrotizing pancreatitis is high risk for progression to necrotizing *infected* pancreatitis. Therapeutic antibiotics are required for treatment of documented infected pancreatic necrosis. Causative pathogens include gram-negative microbes and an increase in gram-positive organisms has been reported.³⁶ Therefore broad-spectrum IV antimicrobials are recommended.

10 The initial treatment of infected pancreatic necrosis is percutaneous catheter or endoscopic (transgastric/transduodenal) drainage with a second drain placement as required. The “step-up” approach consisted of percutaneous drainage followed, if necessary, by minimally invasive retroperitoneal necrosectomy. The minimally invasive step-up approach, as compared with open necrosectomy, reduced the rate of the primary composite endpoint (12% vs. 50%, including major complications [new-onset multiple organ failure or multiple systemic complications, perforation of a visceral organ or enterocutaneous fistula, or bleeding] or death), but the mortality rate did not differ significantly between groups (19% vs. 16%).^{37,38}

11 Lack of clinical improvement after these initial procedures warrants consideration of minimally invasive techniques for pancreatic necrosectomy including video-assisted retroperitoneal debridement (VARD), minimally invasive retroperitoneal pancreatectomy (MIRP), or transluminal direct endoscopic necrosectomy (DEN).³⁹ VARD and MIRP use the tract created by percutaneous drainage catheters as a guide for placement of a laparoscope into the retroperitoneum so that debridement and lavage can be performed under direct visualization. Open necrosectomy is associated with substantial morbidity, but to date no randomized trial has documented superiority of either minimally invasive or open surgical technique. Additional trials are underway to address this ([Algorithm 8-3](#)). See also chapter on Acute Pancreatitis.

SKIN AND SOFT TISSUE INFECTIONS

Skin and soft tissue infections (SSTIs) span a broad spectrum of clinical entities from limited cellulitis to rapidly progressive necrotizing fasciitis, which may be associated with septic shock or toxic shock syndrome and associated organ failure.^{40,41} These SSTIs may result in critical illness and require management in the intensive care unit (ICU).^{42,43} Methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as the most common identifiable cause of severe SSTIs, therefore initiation of empiric anti-MRSA antimicrobials is warranted in all cases of severe SSTIs. In addition, appropriate critical care management, including fluid resuscitation, organ support, and nutritional support are necessary components of treatment of severe SSTIs.

The complex interplay of environment, host, and pathogen is important to consider when evaluating SSTIs and planning therapy. The key to a successful outcome in caring for patients with severe SSTIs is (1) early diagnosis and differentiation of necrotizing versus nonnecrotizing SSTI, (2) early initiation of appropriate empiric broad-spectrum antimicrobial therapy with consideration of risk factors for specific pathogens, (3) “source control,” that is, early aggressive surgical intervention for drainage of abscesses

and debridement of necrotizing soft tissue infections (NSTIs), and (4) pathogen identification and appropriate deescalation of antimicrobial therapy.

Algorithm 8-3. Step-up approach to management of necrotizing infected pancreatitis. (Adapted from Besselink MG, van Santvoort HC, Nieuwenhuijs, et al.; Dutch Acute Pancreatitis Study Group. Minimally invasive ‘step-up approach’ versus maximal necrosectomy in patients with acute necrotizing pancreatitis (PANTER trial): design and rationale of a randomized controlled multicenter trial [ISRCTN13975868]. *BMC Surg* 2006;6:6.)

Table 8-10 Comparison of Old and New Classification of SSTIs by FDA

■ Uncomplicated ■ Superficial infections, such as: ■ simple abscesses ■ impetiginous lesions ■ furuncles ■ cellulitis ■ Can be treated by antibiotics or surgical incision alone	■ Complicated ■ Deep soft tissue, such as: ■ infected ulcers ■ infected burns ■ major abscesses ■ Significant underlying disease state which complicates response to treatment ■ Requires significant surgical intervention and antimicrobials
New FDA Definition (October 2013): ABSSSI defined as bacterial infection of the skin with a lesion size area of at least 75 cm² (lesion size measured by the area of redness, edema, or induration), including the following: ■ Cellulitis/crysipelas: A diffuse skin infection characterized by spreading areas of redness, edema, and/or induration ■ Wound infection: An infection characterized by purulent drainage from a wound with surrounding redness, edema, and/or induration ■ Major cutaneous abscess: An infection characterized by a collection of pus within the dermis or deeper that is accompanied by redness, edema, and/or induration	

From <http://www.fda.gov/ohrms/dockets/98fr/2566dft.pdf>. Accessed January 19, 2016.

Classification of Skin and Soft Tissue Infections

The FDA previously classified SSTIs into two broad categories for the purpose of clinical trials evaluating new antimicrobials for the treatment of SSTIs: **uncomplicated** and **complicated** (Table 8-10). **Uncomplicated** SSTIs include superficial infections such as cellulitis, simple abscesses, impetigo, and furuncles. These infections can be treated by antibiotics and/or surgical incision for drainage of abscess alone. In contrast, **complicated** SSTIs include deep soft tissue infections that require significant surgical intervention, such as infected ulcers, infected burns, and major abscesses, and these patients also have significant underlying comorbidities, that is, disease states which complicate (and usually delay) response to treatment. Complicated SSTIs are a significant clinical problem, in part related to the increasing resistance of infecting bacteria to current antibiotic therapies.

Uncomplicated Skin and Soft Tissue Infections

Uncomplicated SSTIs are associated with **low** risk for life- or limb-threatening infection. These patients can be treated with empiric antibiotic therapy according to likely pathogen and local resistance patterns.

Complicated Skin and Soft Tissue Infections

Complicated SSTIs are associated with **high** risk for life- or limb-threatening infection. In these patients, it is of paramount importance to initiate appropriate and adequate broad-spectrum initial empiric antimicrobial therapy with coverage for MRSA and to consider the need for surgical intervention for abscess drainage or debridement.

Patients with complicated SSTIs require hospitalization for treatment. Specific circumstances that warrant hospitalization include the presence of tissue necrosis, sepsis, severe pain, altered mental status, immunocompromised state, and organ failure (respiratory, renal, hepatic). SSTIs can lead to serious potentially life-threatening local and systemic complications. The infections can progress rapidly and early recognition and proper medical and surgical management is cornerstone of therapy.

12 In October 2013, the FDA changed the SSTI terminology and issued final guidance for the treatment of acute bacterial skin and skin structure infections (ABSSSI).⁴⁴ This guidance defined ABSSSI as cellulitis, erysipelas, wound infection, and major cutaneous abscess. An ABSSSI is defined as a bacterial infection of the skin with a lesion size area of at least 75 cm² (lesion size measured by the area of redness, edema, or induration). The minimum area of involvement of 75 cm² is chosen to select patients with acute bacterial skin infections for which a reliable control drug treatment effect can be estimated for the conduct of new antimicrobial treatment trials. While the FDA generally requires two phase III trials to support approval of drugs to treat ABSSSI, this guidance stated that a single phase III study that is supported by additional independent evidence may suffice.

Patients with the following infection types can be enrolled in ABSSSI clinical trials:

- **Cellulitis/erysipelas:** A diffuse skin infection characterized by spreading areas of redness, edema, and/or induration
- **Wound infection:** An infection characterized by purulent drainage from a wound with surrounding redness, edema, and/or induration
- **Major cutaneous abscess:** An infection characterized by a collection of pus within the dermis or deeper that is accompanied by redness, edema, and/or induration

Unfortunately, this new guidance does not address less serious skin infections, such as impetigo and minor cutaneous abscess, or more serious infections needing more complex treatment regimens, such as infections resulting from animal or human bites, NSTIs, diabetic foot infection, decubitus ulcer infection, myonecrosis, osteomyelitis, and ecthyma gangrenosum.

Early Diagnosis and Differentiation of Necrotizing versus Nonnecrotizing SSTI

Another classification for SSTIs that is commonly used is the differentiation of **NSTIs** from **nonnecrotizing infections**. This differentiation is critical since necrotizing infections warrant prompt aggressive surgical debridement. Clinical clues to the diagnosis of NSTIs are listed in [Table 8-3](#). The differentiation of necrotizing infections from nonnecrotizing infections is critical to achieving adequate surgical therapy.⁴⁵ A clear approach to these infections must allow rapid identification and treatment of NSTIs because they are limb threatening and life threatening.

When clinical “hard clinical signs” (bullae, crepitus, gas on x-ray, hypotension with SBP < 90 mm Hg, or skin necrosis) of NSTI are present, establishing the diagnosis of NSTI is not difficult. However, hard signs of NSTIs are often absent on presentation, thus potentially delaying diagnosis and surgical intervention. Studies have documented that less than 50% of patients with a definitive diagnosis of NSTI presented with “hard clinical signs” of NSTI.⁴⁶ Admission of white blood cell count > 15,400 × 10⁹/L and/or serum sodium < 135 mEq/L was documented to help differentiate NSTI from non-NSTI and aided in early diagnosis.^{47,48} The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is also helpful as a laboratory aid in distinguishing necrotizing from nonnecrotizing SSTIs (see NSTI section below). In retrospective studies CT scan has been shown to have a negative predictive value of 100% and a positive predictive value of 76% in diagnosing NSTI.⁴⁹

If there is any question regarding the possible diagnosis of an NSTI, it is imperative to proceed with surgical intervention and to be certain that the surgical incision is continued down to the fascial and muscle level to make a definitive diagnosis.

Early Initiation of Appropriate Empiric Broad-Spectrum Antimicrobial Therapy with Anti-MRSA Coverage and Consideration of Risk Factors for Specific Pathogens

Antimicrobial therapy is an essential element in the management of severe SSTIs. As in all serious life-threatening infections, it is important to initiate **early** and **appropriate** empiric antimicrobial therapy. It is well established that prompt appropriate treatment of hospitalized infections reduces mortality.² Similar findings were reported in studies of patients with ventilator-associated pneumonia⁵⁰ and sepsis.⁵¹ A study of ICU patients found that the higher mortality rate associated with inappropriate initial therapy is still observed when antibiotics are switched from an inappropriate to an appropriate treatment.⁵²

Furthermore, appropriate and timely antibiotic therapy improves treatment outcomes for SSTIs caused by MRSA.⁵³ In a study of 492 patients with community-onset MRSA SSTIs, 95% of episodes treated with an active antibiotic within 48 hours were treated successfully, compared with an 87% rate of successful treatment in patients who did not receive an active antibiotic. In logistic regression analysis, failure to initiate active antimicrobial therapy within 48 hours of presentation was the only independent predictor of treatment failure. Similarly, in a study of patients admitted to the hospital with MRSA sterile-site infection, multivariate analysis found inappropriate antimicrobial treatment to be an independent risk factor for hospital mortality.⁵⁴

An empiric treatment algorithm for SSTI directed against community-associated MRSA (CA-MRSA) in the emergency department that promotes both the use of antibiotics likely active against CA-MRSA and early incision and drainage of abscesses was examined. Clinical failure occurred in only 3% of cases treated according to the algorithm, compared with 62% of those not treated according to the algorithm. Furthermore, among cases that underwent immediate incision and drainage, initial treatment with antibiotics active in vitro against the MRSA isolate was associated with a decreased clinical failure rate when compared to those treated with inactive antibiotics (0% vs. 67%).⁵⁵

Empiric antibiotic therapy should be initiated in **all** patients with SSTIs. IV broad-spectrum antimicrobial therapy should be initiated when an infection is severe or progresses rapidly, when there are signs of systemic illness, when the patient has comorbidities or is immunosuppressed, for very old or young patients, when an abscess cannot be completely drained, and when the infection does not respond to incision and drainage.⁵⁶

Timely initiation of antimicrobial therapy is also important in the treatment of severe SSTIs, particularly if associated with septic shock. In a study of 2,731 adult patients with septic shock, a strong relationship between the delay in effective antimicrobial initiation and in-hospital mortality was noted.⁴ Administration of an antimicrobial effective for isolated or suspected pathogens within the first hour of documented hypotension was associated with a survival rate of 79.9%. Each hour of delay in antimicrobial administration over the ensuing 6 hours was associated with an average decrease in survival of 7.6%. By the second hour after onset of persistent/recurrent hypotension, in-hospital mortality rate was significantly increased relative to receiving therapy within the first hour. In multivariate analysis (including Acute Physiology and Chronic Health Evaluation II score and therapeutic variables), time to initiation of effective antimicrobial therapy was the single strongest predictor of outcome. Interestingly, only 50% of septic shock patients received effective antimicrobial therapy within 6 hours of documented hypotension.

Necrotizing Soft Tissue Infections

NSTIs are aggressive soft tissue infections that cause widespread necrosis, and can include necrotizing cellulitis, fasciitis, and myositis/myonecrosis.^{57,58} Establishing the diagnosis of NSTI can be the main challenge in treating patients with NSTI, and knowledge of all available tools is key for early and accurate diagnosis.⁵⁹ There have been a number of recent advances in the definition, pathogenesis, diagnostic criteria, and treatment of NSTIs.^{60,61}

Patients with NSTIs require prompt aggressive surgical debridement, appropriate IV antibiotics, and intensive support. Despite aggressive treatment, their mortality and morbidity rates remain high, with some series reporting mortality rates of 25% to 35%.⁶² A high index of suspicion should be used in conjunction with laboratory and imaging studies to establish the diagnosis as rapidly as possible. Successful treatment requires early, aggressive surgical debridement of all necrotic tissue, appropriate broad-spectrum systemic antibiotic therapy, and supportive care (fluid resuscitation, organ and critical care support) to maintain oxygenation and tissue perfusion. Delayed definitive debridement remains the single most important risk factor for death. Early operative debridement is the major determinant of outcome in NSTIs.

A recent single-institution series of 166 patients documented that the overall mortality rate was 17% and limb loss occurred in 26% of patients with extremity involvement.⁶³ Independent predictors of mortality included white blood cell count greater than $30,000 \times 10^3/\mu\text{L}$, creatinine level greater than 2 mg/dL, and heart disease at hospital admission. Independent predictors of limb loss included heart disease and shock (systolic blood pressure < 90 mm Hg) at hospital admission. Clostridial infection was an independent predictor for both limb loss and mortality and was highly associated with IV drug use and a high rate of leukocytosis on hospital admission.

A 30-day postoperative mortality risk calculator for NSTI was developed using the NSQIP which identified seven independent variables that correlated with mortality: age older than 60 years, functional status, requiring dialysis, American Society of Anesthesiologists (ASA) class 4 or higher, emergent surgery, septic shock, and low platelet count. The receiver operating characteristic area was 0.85, which indicated a strong predictive model that can aid physicians in the decision-making process.⁶⁴

13 Early operative debridement is the major determinant of outcome in NSTIs. However, early recognition of NSTIs is difficult clinically. A novel diagnostic scoring system for distinguishing NSTIs from other severe soft tissue infections based on laboratory tests routinely performed for the evaluation of severe SSTIs is called the LRINEC score (Table 8-11).⁶⁵ The LRINEC score was initially developed in a retrospective observational study including 145 patients with necrotizing fasciitis and 309 patients with severe cellulitis or abscesses admitted to the 2 tertiary care hospitals. The cutoff value for the LRINEC score was 6 points with a positive predictive value of 92% and negative predictive value of 96%. The LRINEC score is a robust score capable of detecting clinically early cases of necrotizing fasciitis. The variables used are routinely measured to assess severe soft tissue infections. Patients with a LRINEC score of ≥ 6 should be carefully evaluated for the presence of necrotizing fasciitis.

Table 8-11 The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) Score

Variable, Units	Score
C-reactive protein, mg/L	
<150	0
≥ 150	4
Total white cell count, per mm ³	
<15	0
15–25	1
>25	2
Hemoglobin, g/dL	
>13.5	0
11–13.5	1
<11	2
Sodium, mmol/L	
≥ 135	0
≤ 135	2
Creatinine, $\mu\text{mol/L}$	
≤ 141	0
>141	2
Glucose, mmol/L	
≤ 10	0
>10	1

The maximum score is 13; a score ≥ 6 should raise the suspicion of necrotizing fasciitis and a score of ≥ 8 is strongly predictive of this disease.

Since the initial development of the LRINEC score, a number of other cohort studies have validated its utility in the diagnosis of NSTIs. A multicenter study in 229 patients with NSTIs from 2002 to 2005 reported an overall mortality rate of 16% and amputation rate of 26%. This study also documented that a LRINEC score ≥ 6 was associated with a higher rate of both mortality and amputation.⁶⁶

Diagnostic Imaging in Necrotizing Soft Tissue Infections

NSTIs necessitate prompt aggressive surgical debridement for satisfactory treatment in addition to antimicrobial therapy. Because of the rapidly progressive and potentially fatal outcome of this condition, if imaging cannot be performed expeditiously, delaying treatment is not justified. Plain film findings may reveal extensive soft tissue gas. CT examination can reveal asymmetric thickening of deep fascia in association with gas, and associated abscesses may also be present. MR imaging can also assist in the diagnosis of NSTIs.⁶⁷ MR imaging has been documented to effectively differentiate between necrotizing and nonnecrotizing infections of the lower extremity and other areas of the body, but should not delay prompt surgical intervention in NSTIs management.^{68–70}

Microbiology of Necrotizing Soft Tissue Infections

Necrotizing fasciitis and myonecrosis are typically caused by infection with group A streptococcus (GAS), *Clostridium perfringens*, or, most commonly, aerobic and anaerobic organisms as part of a polymicrobial infection that may include *S. aureus*. In case series, CA-MRSA has recently been described as a predominantly monomicrobial cause of necrotizing fasciitis.^{71,72} A retrospective review of patients presenting with necrotizing fasciitis indicated that MRSA was the most common pathogen, accounting for one-third of the organisms isolated.⁷³

NSTIs have been classified into two types, either polymicrobial (**type I**) or monomicrobial (**type II**). Polymicrobial infections are more common, due to both aerobic and anaerobic organisms, and commonly occur in the trunk and perineum. NSTIs that are monomicrobial in origin commonly occur in the limbs and are typically caused by infection with GAS, *C. perfringens*, or *S. aureus*. NSTIs are categorized into these two specific types based on the microbiologic etiology of the infection, and this classification does impact on the specific antimicrobial agents required for treatment of these NSTIs. Increasingly, MRSA has been identified as the causative microbe in NSTIs, but a separate category for this NSTI does not currently exist.⁷⁴⁻⁷⁸ Given this finding, anti-MRSA empiric antimicrobial therapy should be initiated in all patients with NSTIs and pathogen-directed antimicrobial therapy considered once tissue culture results are available.

Uncommon microbiologic causes of NSTIs and primary sepsis include *Vibrio* and *Aeromonas* species, virulent gram-negative bacteria, and members of the Vibrionaceae family that thrive in aquatic environments.⁷⁹ These NSTIs are likely to occur in patients with hepatic disease, diabetes, and immunocompromised conditions.⁸⁰ These organisms are found in warm sea waters and are often present in raw oysters, shellfish, and other seafood. The diagnosis of vibrio NSTIs should be suspected when a patient has the appropriate clinical findings and a history of contact with seawater or raw seafood.⁸¹ Early fasciotomy and culture-directed antimicrobial therapy should be aggressively performed in those patients with hypotensive shock, leukopenia, severe hypoalbuminemia, and underlying chronic illness, especially a combination of hepatic dysfunction and diabetes mellitus. The rates of amputation and mortality are very high in these patients, and early definitive management is of paramount importance.⁸²⁻⁸⁴ A study of 125 patients identified that a LRINEC score of 2 or greater and the presence of hemorrhagic bullous/blistering lesions in patients with *Vibrio vulnificus* SSTI are associated with an 12-fold increased risk for the presence of NSTI and necrotizing fasciitis.⁸⁵

Pyomyositis

Myositis is a rare infection that may lead to serious and potentially life-threatening local and systemic complications.⁸⁶ The infection can progress rapidly, and early recognition and proper medical and surgical management is therefore the cornerstone of therapy. With the increasing prevalence of community-associated MRSA as a pathogen in severe SSTIs, pyomyositis is more common than in past years.^{87,88} Myositis often occurs in muscle sites that have been compromised by injury, ischemia, malignancy, or surgery. The predominant pathogens are *S. aureus*, GAS, gram-negative aerobic and facultative bacilli, and the indigenous aerobic and anaerobic cutaneous and mucous membranes local microflora.

CT scan imaging is a rapid and sensitive diagnostic test and commonly demonstrates diffuse enlargement of the involved muscle and may demonstrate the presence of fluid or gas collections within the muscle suggesting the presence of abscesses. MRI is more sensitive in showing early inflammatory changes prior to development of abscesses in myositis.⁸⁹ Emergency surgical exploration is warranted in order to define the nature of the infective process which is accomplished by direct examination of the involved muscles. Surgical intervention is required to perform appropriate abscess drainage and debridement and also to evaluate for necrotizing myositis. Fasciotomies and extremity amputation are sometimes necessary.

SURGICAL SITE INFECTIONS

Epidemiology

SSI is the leading nosocomial infection among surgical patients and the second most common nosocomial infection overall. In the United States, greater than 40 million inpatient and outpatient surgical procedures are performed each year and 2% to 5% are complicated by SSIs. SSIs result in increased length of stay (7 days) and additional cost (\$400 to \$2,600 per infection; total \$130 to \$845

million per year).^{90–93} Among the four healthcare-associated infections (pneumonia, SSI, urinary tract infection, and bloodstream infection), SSIs are the second most common healthcare-associated infection, accounting for 17% of all healthcare-associated infections among hospitalized patients. A similar rate was obtained from the National Healthcare Safety Network (NHSN) hospitals reporting data in 2006–2008 (15,862 SSI following 830,748 operative procedures, with an overall rate of nearly 2%).⁹⁴

Definitions

SSIs are defined in three specific categories by the Centers for Disease Control and Prevention (CDC), including superficial incisional SSI, deep incisional SSI, and organ/space SSI (Fig. 8-4, Table 8-12), dependent on the depth of the infection at the surgical incision site. In addition, the SSI must occur within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operative procedure. More specific criteria regarding these definitions are available in the CDC Guideline for Prevention of Surgical Site Infection.⁹⁵

Risk Factors for Surgical Site Infection

SSI risk is strongly associated with wound classification, with low risk for SSI in *clean* and *clean-contaminated* wound classes, and high risk for SSI in *contaminated* and *dirty-infected* wound classes. Three independent variables have been shown to be associated with SSI risk, initially developed by the National Nosocomial Infections Surveillance System (NNIS). The NHSN was established in 2005 to integrate and supersede three legacy surveillance systems at the CDC: the NNIS system, the Dialysis Surveillance network (DSN), and the National Surveillance System for Healthcare Workers (NaSH). Similar to the NNIS system, NHSN facilities voluntarily report their healthcare-associated infection surveillance data for aggregation into a single national database.

The NHSN SSI Risk Index includes an ASA score greater than 2, classification of wound as contaminated or dirty, and prolonged duration of operation.^{96,97} Although the risk of infection increases within the wound classification, it has been shown to be also dependent within each wound class on the NNIS classification.

Table 8-12 CDC/NHSN Classification of Surgical Site Infections (SSIs)

Type of SSI	Definition
Superficial incisional	Infection occurs within 30 d after the operative procedure and involves only skin and subcutaneous tissue of the incision and patient has at least one of the following: - purulent drainage from the superficial incision - organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision - at least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat, and superficial incision is deliberately opened by surgeon and is culture positive or not cultured. A culture-negative finding does not meet this criterion - diagnosis of superficial incisional SSI by the surgeon or attending physician
Deep incisional	Infection occurs within 30 d after the operative procedure if no implant ^a is left in place or within 1 yr if implant is in place and the infection appears to be related to the operative procedure and involves deep soft tissues (e.g., fascial and muscle layers) of the incision and patient has at least one of the following: - purulent drainage from the deep incision but not from the organ/space component of the surgical site - a deep incision spontaneously dehisces or is deliberately opened by a surgeon and is culture positive or not cultured when the patient has at least one of the following signs or symptoms: fever (38°C), or localized pain or tenderness. A culture-negative finding does not meet this criterion. - an abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination - diagnosis of a deep incisional SSI by a surgeon or attending physician

^aImplant: A nonhuman-derived object, material, or tissue (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during an operative procedure and is not routinely manipulated for diagnostic or therapeutic purposes. From Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of healthcare-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–332.

Figure 8-4. Surgical site infection (SSI) definitions by CDC.

Cross-section of the abdominal depicted.

Superficial incisional SSI involves only the skin and subcutaneous tissue layer of the incision

Deep incisional SSI involves deep soft tissues (e.g., fascia and muscle layers) of the incision

Organ/space SSI involves any part of the body, excluding the skin incision, fascia or muscle layers, that is opened or manipulated during the operative procedure (e.g., intra-abdominal abscess or thoracic empyema)

Basic SSI Risk Index

The index used in NHSN assigns surgical patients into categories based on the presence of three major risk factors:

1. Operation lasting more than the duration cut point hours, where the duration cut point is the approximate 75th percentile of the duration of surgery in minutes for the operative procedure.
2. Contaminated (class 3) or dirty/infected (class 4) wound class.
3. ASA classification of 3, 4, or 5.

The patient's SSI risk category is simply the number of these factors present at the time of the operation.

The laparoscopic surgical approach is associated with decreased SSI incidence, and a modified risk index (category 1 when procedure was performed with a laparoscope) has been created to address this approach.

Additional patient-specific risk factors for SSI have also been identified that are not included in this risk index, including the presence of anemia, blood transfusion intraoperatively, and colonization with resistant pathogens.^{97,98} This SSI Risk Index warrants reevaluation for the future, particularly with regard to resistant pathogens and other patient-specific risk factors that are not modifiable prior to surgical intervention. It is of paramount importance to include an SSI risk assessment in all future clinical trials where SSI is a primary outcome measure.

Surgical Site Infection Prevention

Preventive measures for SSI include antimicrobial prophylaxis, sterilization methods, proper ventilation of operating rooms, use of barriers, no shaving, clipping if hair removal is required, proper surgical skin preparation and surgical techniques, maintenance of normothermia, glycemic control, and the provision of supplemental oxygen.⁹³ The National Surgical Infection Prevention (SIP) project was initiated as the first component of the Surgical Care Improvement Project (SCIP). Initiated in 2003, the SCIP partnership sought to substantially reduce surgical mortality and morbidity through collaborative efforts.

Despite evidence of effectiveness of preoperative antimicrobials for SSI prevention and the publication of guidelines for antimicrobial prophylaxis, it was recognized that use was often suboptimal. As part of the SIP initiative, three SIP performance measures were developed:

- **SIP-1: Antibiotic timing:** Proportion of patients in whom IV antimicrobial prophylaxis is initiated within 1 hour before incision
- **SIP-2: Antibiotic selection:** Proportion of patients are given prophylactic antimicrobials consistent with published guidelines

■ SIP-3: Antibiotic discontinuation within 24 hours: Proportion of patients whose antimicrobial prophylaxis is discontinued within 24 hours after surgery

Numerous studies document that antimicrobial prophylaxis for SSI is most effective when provided 30 to 60 minutes prior to the initial surgical incision, allowing adequate blood and tissue concentrations at the time of skin incision. Risk of SSI increases when antimicrobial prophylaxis is given too early (more than 2 hours prior to skin incision) or too late (after skin incision). In a recent study of 4,472 patients, SSI risk increased incrementally as the interval of time between antibiotic infusion and the surgical incision increased. These data from a large multicenter collaborative study confirmed lower SSI risk when surgical antimicrobial prophylaxis with cephalosporins and other antibiotics with short infusion times were given within 30 minutes prior to surgical incision.⁹⁹

In addition, the correct antimicrobial must be administered to cover the potential causative pathogens, dependent on the surgical procedure performed. The SCIP pocket card (Table 8-13) provides a list of the recommended preoperative antimicrobials for specific surgical procedures. The recent publication of the “Clinical practice guidelines for antimicrobial prophylaxis in surgery” by the American Society of Health-System Pharmacists, Infectious Diseases Society of America, Surgical Infection Society, and Society for Healthcare Epidemiology of America provide evidence-based national recommendations.¹⁰⁰

The first report of the National SIP Project baseline results from a systematic random sample of 34,133 medicare inpatients undergoing surgery in US hospitals in 2001 documented that only 55.7% of patients received a dose of parenteral antimicrobial prophylaxis within 1 hour before surgical incision. Antimicrobial agents consistent with published guidelines were administered to 92.6% of patients and antimicrobial prophylaxis was discontinued within 24 hours of surgery end time for only 40.7% of patients. Interestingly, only 28% of these surgical patients had compliance with all three of these performance measures.¹⁰¹

Table 8-13 Recommended Preoperative Antimicrobials for Specific Surgical Procedures

Prophylactic Antibiotic Regimen Selection for Surgery	Prophylactic Antibiotic Regimen Selection for Surgery
Surgical procedure: CABG, other cardiac or vascular	Surgical procedure: hip/knee arthroplasty
Approved antibiotics Cefazolin, cefuroxime, or vancomycin ^b If β-lactam allergy: vancomycin ^a or clindamycin ^a	Approved antibiotics Cefazolin or cefuroxime or vancomycin ^b If β-lactam allergy: vancomycin ^a or clindamycin ^a
Surgical procedure: hysterectomy	Surgical procedure: colon
Approved antibiotics Cefotetan, cefazolin, ceftioxin, cefuroxime, or ampicillin/sulbactam If β-lactam allergy: clindamycin + aminoglycoside, or clindamycin + quinolone, or clindamycin + aztreonam OR metronidazole + aminoglycoside, or metronidazole + quinolone	Approved antibiotics Cefotetan, ceftioxin, ampicillin/sulbactam, or cefepime OR cefazolin or cefuroxime + metronidazole If β-lactam allergy: clindamycin + aminoglycoside, or clindamycin + quinolone, or clindamycin + aztreonam OR metronidazole with aminoglycoside, or metronidazole + quinolone
Surgical procedure: special considerations	Surgical procedure: special considerations

^aFor cardiac, orthopedic, and vascular surgery, if the patient is allergic to β-lactam antibiotics, vancomycin or clindamycin is acceptable substitute.
^bVancomycin is acceptable with a physician/APN/PA/pharmacist documented justification for its use (see data element *Vancomycin*).
^cA single dose of ertapenem is recommended for colon procedures.

We have truly made remarkable progress in the United States with appropriate perioperative antimicrobial prophylaxis since that initial published report. Compliance with SIP-1 measure (antibiotics within 60 minutes prior to incision) increased from 55.7% to 91.6%; compliance with SIP-2 measure (guideline antibiotics) increased from 92.6% to 95.8%; and compliance with SIP-3 (antibiotics discontinued) increased from 40.7% to 87.7%.

Additional Strategies for Surgical Site Infection Prevention

Surgical Hand Antisepsis

Surgical hand antisepsis, to destroy bacteria, is routinely carried out before undertaking invasive procedures. A recent review of 10 trials confirmed that alcohol rubs used in preparation for surgery by the surgical team are as effective as aqueous scrubbing in SSI prevention. There is no evidence to

suggest that any particular alcohol rub is better than another. Evidence from four studies suggests that chlorhexidine gluconate–based aqueous scrubs are more effective than povidone iodine–based aqueous scrubs in terms of the numbers of bacterial colony–forming units on the hands.¹⁰²

Chlorhexidine as Skin Surgical Site Preparation

Preoperative skin antisepsis of the surgical site is performed to reduce the risk of SSI by removal of skin microorganisms. A review of six randomized controlled trials identified significant heterogeneity and the trial results could not be pooled. There was no evidence of a benefit in four trials associated with the use of iodophor-impregnated drapes.¹⁰³ More recent studies have documented that chlorhexidine provided superior skin decontamination compared to povidone-iodine.^{104–107} The most recent Cochrane systematic review found evidence that preoperative skin preparation with 0.5% chlorhexidine in alcohol was associated with lower SSI rates following clean surgery than alcohol-based povidone-iodine paint.¹⁰⁸

Appropriate Hair Removal

The preparation of the surgical site has traditionally included the routine removal of body hair, however, some studies have suggested that this is deleterious. A Cochrane systematic review of 11 randomized clinical trials, and 3 trials ($n = 3,193$) comparing shaving with clipping, found that there were statistically more SSIs with shaving than clipping. If it is necessary to remove hair, clipping results in fewer SSIs than shaving using a razor.¹⁰⁹

Normothermia Maintenance During Surgery

Perioperative hypothermia is common and adversely affects clinical outcomes. The primary beneficial effects of warming are mediated through increased blood flow and oxygen tension at the tissue level. Hypothermia may facilitate SSI in two ways. First, sufficient intraoperative hypothermia triggers thermoregulatory vasoconstriction. Second, considerable evidence indicates that mild core hypothermia directly impairs immune function including T-cell–mediated antibody production and nonspecific oxidative bacterial killing by neutrophils. Randomized controlled trials have documented that perioperative warming is associated with a significant reduction in SSI and this simple SSI preventive strategy should be implemented in all surgical patients.^{110–112}

Normoglycemia Maintenance During Surgery

Perioperative hyperglycemia has been associated with increased SSIs and previous recommendations have been to treat glucose levels above 200 mg/dL. Recent studies have questioned the optimal glycemic control regimen to prevent SSIs. A recent Cochrane Database systematic review included five randomized controlled clinical trials with a total of 773 patients randomized. Due to heterogeneity in patient populations, perioperative period, glycemic target, route of insulin administration, and definitions of outcome measures, combination of the results of the five trials into a meta-analysis was not appropriate. The authors concluded that there is insufficient evidence to support strict glycemic control in the intra- and postoperative period among surgical patients for the prevention of SSIs.¹¹³ A Cochrane review of 12 trials that randomized diabetic patients to intensive or conventional glycemic control perioperatively concluded that no significant differences were identified in patients with diabetes mellitus. However, posthoc analysis indicated that intensive glycemic control was associated with greater incidence of hypoglycemia episodes.¹¹⁴

There are no randomized trials evaluating immediate preoperative glycemic control in any setting or intra/postoperative glycemic control in non-ICU patients. High-quality evidence for strict glycemic control in the intra- and/or postoperative period among surgical ICU patients, cardiac and noncardiac, to reduce SSIs, independent of other potential benefits, is also lacking. Further large, adequately powered, well-designed randomized trials are necessary to identify the ideal target for perioperative glycemic control in patients at high risk for SSIs. Future trials should report all nosocomial infections as well as SSIs. Given the heterogeneity seen in the included trials, it would appear that trials should be targeted at very specific populations and attempts to draw broader conclusions should not be made. At present, we should strive at least to maintain blood glucose <200 mg/dL in the perioperative period in our surgical patients.

Supplemental Oxygen in Perioperative Period

Several randomized controlled trials have been conducted to assess the benefit of perioperative supplemental oxygen in SSI reduction, yet meta-analyses have arrived at different conclusions.^{115–117} On

careful review, a number of problems with the conduct of these trials are noted: (1) SSI definition was not consistent with CDC definitions; (2) the interval for assessment of SSI was variable, ranging from 15 to 30 days; (3) SSI was captured retrospectively in some studies and was not always a primary outcome measure; (4) no assessment of the patient's individual risk factors for SSI was performed; (5) no control of perioperative antibiotic prophylaxis timing or selection was performed; and (6) there was variable provision of high FiO₂ supplemental oxygen in each of the studies.¹¹⁸

The first institutional priority should be to universally implement all the evidence-based practices that reduce SSIs. The “SSI Bundle” from the Institute for Healthcare Improvement includes (1) appropriate use of antibiotics, (2) appropriate hair removal, (3) perioperative glucose control, and (4) perioperative normothermia.¹¹⁹ The additional provision of increased inspired oxygen concentrations should be considered as an additional quality improvement measure, particularly in institutions with high SSI rates. A collaborative of 44 hospitals implemented the SSI preventive strategies discussed above and documented a significant reduction in the SSI rate, from 2.3% to 1.7%, representing a 27% reduction from the first to the last 3 months of the 1-year project.¹²⁰ Finally, prospective SSI surveillance, including postdischarge surveillance, should be instituted to obtain accurate information regarding institutional SSI rates.¹²¹

Surgical Site Infection and Colorectal Surgery

Surgical care bundles have been documented to be effective in reducing SSIs in patients undergoing colorectal surgery and therefore should be implemented.¹²² Surgeons have held a long-standing belief that mechanical bowel preparation is an efficient strategy to reduce SSI and anastomotic leak rates following elective colorectal surgery. Recent systematic reviews have found that there is no statistically significant evidence that patients benefit from mechanical bowel preparation either in SSI or anastomotic leak rates.¹²³ In contrast, the use of nonabsorbable enteral antimicrobials covering aerobic and anaerobic colonic bacteria, in addition to IV preoperative antibiotics, is associated with a significant reduction in SSI by at least 75%.^{124–126}

Treatment of Surgical Site Infection

Once superficial or deep incisional SSI is diagnosed, “pathogen identification” is of paramount importance. In years past, the surgical incision was opened and dressing changes were initiated with no culture of the surgical site obtained. In today's era of multidrug-resistant pathogens, a Gram stain and culture of the surgical site should always be obtained in order to determine the optimal antimicrobial therapy that is required for SSI treatment.

SSI treatment includes four strategies for successful treatment: (1) early empiric antimicrobial therapy; (2) decision-making regarding whether the surgical site should be opened; (3) pathogen identification; and (4) deescalation of antimicrobial therapy once culture results are available.

For organ/space SSI, “source control” and “pathogen identification” are both high priorities in order to achieve successful treatment. In the case of intra-abdominal abscess, source control can be provided by either interventional radiology percutaneous drainage or open surgical drainage of the abscess. Abscess fluid should be sent for Gram stain and culture, and empiric antimicrobial treatment should be deescalated once culture results are available.

Current Challenges in Surgical Site Infection

There are a number of growing challenges in SSI, including resistant pathogens, our increasingly elderly population, more patients with chronic diseases or immunocompromised states undergoing surgery, and increasing patients undergoing surgery for solid organ transplantation and placement of prosthetic devices. MRSA was reported to be the most common cause of SSI in vascular surgery patients ($n = 772$ over a 2-year period) in 2004.^{127,128} MRSA has emerged as the leading cause of postoperative infection in vascular surgery patients, and is associated with substantial morbidity, increased hospital length of stay, and higher incidences of amputation and graft removal.

Comparison of the causative pathogens for SSI in US hospitals documents that *S. aureus* increased from 22.5% (1986–2003) to 30% (2006–2007), with MRSA now the leading causative pathogen, comprising 49.2% of all isolates.^{128,129} In a study of 8,302 patients readmitted to US hospitals with culture-confirmed SSI from 2003 to 2007, it was noted that the proportion of infections due to MRSA significantly increased from 16.1% to 20.6% and was associated with higher mortality rates, longer length of stay, and higher hospital costs.¹³⁰ Based on this important finding, some have strongly advocated for active screening for nasal carriage of MRSA prior to elective surgery with modification of

antimicrobials for SSI prevention based on those results.^{131–133} Eradication of MRSA before surgery appears to lower SSI rates due to MRSA and is recommended.^{134,135} In contrast, a prospective interventional cohort study that employed a universal rapid MRSA admission screening strategy among 21,754 surgical patients at a Swiss teaching hospital reported that nosocomial MRSA infection, including SSI, did not decrease, but relatively low rates of MRSA infection were present at the start of this study.¹³⁶

An “MRSA bundle” has been developed including five components:

1. MRSA nasal screening of patients upon admission, transfer, and discharge using PCR;
2. contact isolation of positive patients;
3. standardized hand hygiene;
4. cultural transformation campaign with staff and leadership engagement through positive deviance; and
5. ongoing monitoring of process and outcome measures.

Implementation of the MRSA bundle was associated with a significant decrease in MRSA transmission from 5.8 to 3.0 per 1,000 bed-days, significant reduction in MRSA nosocomial infections (2.0 to 1.0 per 1,000 bed-days), and a significant decrease in overall SSIs, with a 65% reduction in orthopedic MRSA SSIs and a 1% decrease in cardiac MRSA SSIs.¹³⁷

The advent of CA-MRSA^{138,139} has also significantly impacted SSI. Recent studies document that CA-MRSA is replacing traditional healthcare-associated or nosocomial MRSA strains in SSI among inpatients.¹⁴⁰ A report from a large community hospital in St. Louis, MO, examined the rates of SSI due to *S. aureus* in a total of 122,040 surgical procedures in an earlier period (2003–2006) versus later period (2006–2007). MRSA was identified as the SSI pathogen in 40% of all inpatients in both time periods. Interestingly, the percentage of clindamycin-susceptible MRSA (distinguishing CA-MRSA) as an SSI causative pathogen for inpatients rose from 9% in the early period to 19% in the later period. This increase in the rate of CA-MRSA SSI was observed only among inpatients, not among ambulatory patients. Similarly, CA-MRSA has emerged as a leading cause of healthcare-associated infections among patients with prosthetic joint SSIs.¹⁴¹

The use of perioperative intranasal mupirocin for SSI prevention, particularly in patients with MRSA nasal colonization, remains controversial. Reviews of multiple clinical trials documented that no reduction in SSI was seen in general surgery or cardiac surgery patients; however, in nongeneral surgery patients the use of mupirocin was associated with a reduction in SSI.^{134,135,142}

Chapter 9

Shock

Joseph Cuschieri and Darren Bowe

Key Points

- 1 Shock is the clinical syndrome that results from inadequate tissue perfusion from numerous causes: hypovolemic, cardiogenic, extracardiac obstructive, and distributive.
 - 2 Hypovolemic shock due to ongoing blood and/or plasma loss leads to progressive cardiovascular deterioration, ultimate hypotension, oliguria, confusion, irreversible cell injury, and death.
 - 3 Cardiogenic shock results in decreased tissue perfusion due to intrinsic pump failure.
 - 4 Extracardiac obstructive shock attenuates cardiac pump function due to external compression of inflow and outflow (tamponade, tension pneumothorax, etc.).
 - 5 Septic and traumatic shock, forms of distributive shock, are systemic inflammatory responses to infection or tissue injury with cellular breakdown, producing severe hypotension requiring massive volume resuscitation and high risk of multiple organ failure and death.
 - 6 Complications of an episode of shock include ischemia–reperfusion injury from oxidant stress; potential secondary immunosuppression with enhanced nosocomial infection risk; hypothermia and coagulopathy; and multiple organ failure syndrome, including abdominal compartment syndrome (ACS).
 - 7 Treatment of shock requires goal-directed volume resuscitation with treatment of the underlying etiology and careful monitoring of adequacy of end-organ perfusion to avoid under- and overresuscitation.
-

1 The current accepted concept of shock was first described in 1929 by Walter B. Cannon¹ as inadequate blood flow that results in cellular hypoxia. Persistence of cellular hypoxia results in dysfunction at both cellular and organ levels. Although shock can result from a number of etiologies, it was Blalock who first described the four major causes we still refer to today, which are hematogenic, neurogenic, cardiogenic, and vasogenic.²

Prior to this, the concept of shock was not understood since the nature and purpose of the heart and circulatory system were either unknown or misunderstood. Galen was the first to explore the purpose of the heart and circulatory system. He proposed that the arteries carried blood, not air, as previously thought, away from the heart. However, he incorrectly believed that arterial blood within the circulatory system subsequently dissolved in the body to release nutrients. Blood returning to the heart was not due to recirculation, but rather was rapidly remanufactured by the liver. Additionally, since much of his dissection work was carried out in frogs, he concluded falsely that the heart had only two chambers and blood passed from the right to left chamber through invisible pores in the septum.³

These conclusions remained unchallenged for nearly 1,500 years until Vesalius, in the 17th century. Through a series of dissections, he demonstrated that blood did not flow directly from the right to left ventricle. Although he provided elaborate drawings of the body's network of blood vessels, he did not anticipate that blood circulated through the body and was unable to discern the heart's purpose. Shortly thereafter, Harvey moved beyond anatomy and studied physiology; he discovered the closed nature of the circulation and concluded that the heart was the main pumping mechanism. Although the microscope had not yet been invented, he proposed the existence of capillaries that connect the arterial and venous system.³

Due to this improved understanding of the circulatory system, the condition of shock due to blood loss and other etiologies were carefully being observed and explored. During the 18th century, military surgeons such as Henri le Dran (1740) noted that injured soldiers left unattended for several hours suddenly deteriorated as if there had been a *secousse* (jolt) to the system, which probably led to use of the word “shock.”¹ Surgeons began to notice that even when a wounded extremity was amputated, the physiologic effects of the injury often continued, and shock was increasingly recognized as a distinct

systemic syndrome from the wound itself.³

Eventually, Cannon and then Blalock described our current concept of shock and its attributed systemic effects. In fact, Blalock was the first to recognize the third-space fluid loss that follows shock resuscitation that is greater than the quantity of initial blood loss.⁴ As a result, therapy began to focus not only on restoring intravascular volume but also on replacing fluid lost to the interstitium with a balanced salt solution. Investigators then became increasingly intrigued by the fact that, at some point, shock becomes irreversible and is no longer responsive to further volume resuscitation. As stated more than 60 years ago by Wiggers, “at a certain stage adequate circulation cannot be restored by merely filling the system, as one does an automobile radiator.”⁵ At some point, as had been observed multiple times previously, the initiating event (e.g., wound, infection, cardiac dysfunction) is no longer the primary threat. Other “unknown” factors sustain the shock state, blood pressure cannot be restored, improvements are only transient, and death occurs shortly thereafter due to progressive organ dysfunction.

The current concept of shock has led to a reclassification into four distinct groups – hypovolemic, cardiogenic, extracardiac obstructive, and distributive – that may occur independent of each other, or more characteristically synergistic with each other.⁶ Early recognition and prompt treatment are essential to modern treatment. If delayed, uncorrected hypovolemia and critical oxygen delivery deficits occur that lead to irreversible shock. However, it is believed that future therapies will move beyond simple recognition and fluid resuscitation. Thus, investigators are increasingly looking to gain an understanding of the chain of events that occur, which lead to organ damage and irreversibility. This chapter describes these events, discusses the therapeutic approaches utilized in current management, and offers a brief perspective on what may lie ahead in the future.

EVALUATION OF SHOCK

Shock is easily recognized by even the most inexperienced caregiver after the compensatory mechanisms have been overcome (Table 9-1). However, it is more difficult to recognize the patient in compensated shock, who presents with vital signs that are almost normal. It is critically important to the patient’s ultimate outcome that recognition and treatment of shock occur before decompensation. The clinical assessment must be guided by the knowledge that the severity of symptoms and signs of shock vary between patients and the type of shock present. The patient is evaluated based on clinical appearance, hemodynamic measurements, physiologic responses, and biochemical analyses.

Early during various shock states, vasoconstriction frequently causes the skin to be cool leading to poor capillary refill. However, this must be contrasted to shock states induced by either neurogenic or septic states in which vasodilation is present causing the skin to be warm, with good capillary refill. Common to the various shock states is the presence of hyperventilation, a compensatory response due to progressive metabolic acidosis. As shock progresses, mental status changes occur, and decreased cerebral blood flow and increased catecholamine stimulation may lead to anxiety and restlessness. With continued shock, lethargy may result. True coma, however, seldom results due to shock alone, unless coincident complete cardiovascular collapse occurs, and is usually associated with other conditions such as direct brain injury or severe hypoxia.⁷ This includes evaluation of the rate and character of the pulse; the blood pressure; and, in some cases, the central venous pressure (CVP), pulmonary artery pressure, pulse pressure variation (PPV), and echocardiography.⁸

The hemodynamic assessment should include evaluation of the rate and character of the pulse; the blood pressure; and, in some cases, the CVP, pulmonary artery pressure, and PPV.⁸ Tachycardia is a normal response to volume loss but also to pain, anxiety, and fear, all of which are commonly present. Assessment of the pulse may be helpful in determining the proper diagnosis. Because of the body’s ability to compensate for hypovolemia, changes in blood pressure do not occur reliably until nearly 30% of blood volume has been lost. However, the pulse pressure usually narrows, even in compensated shock, because of the effects of vasoconstriction on the diastolic blood pressure. Importantly, the CVP reflects the adequacy of and not the true blood volume, and the state of the venous tone. Changes in CVP in response to treatment or from continuing hemorrhage are more revealing than a solitary measurement. However, this concept remains debatable. Because of the misuse or overuse of pulmonary artery catheters (PACs), routine placement no longer occurs and has been associated with increased morbidity.⁹ As a result, invasive monitoring using PPV, and noninvasive measures such as echocardiography have become more commonly used.¹⁰

An indirect but extremely valuable measure of perfusion and volume status is urine output. A urinary

catheter should be inserted in every patient being evaluated for shock. Hourly urine output should be 0.5 to 1 mL/kg for adult patients, at least 1 mL/kg for most pediatric patients, and 1 to 2 mL/kg for patients younger than 2 years of age. Lack of adequate urine output in the setting of previous normal kidney function should cause the caregiver to be highly concerned about the continued presence of inadequate perfusion and cellular hypoxia.

Although each of the physical examination components are important in the identification of shock, used alone these factors can fail to diagnose compensated shock. As a result, biochemical markers are used as a means to identify shock in its early stages. Biochemical analysis of shock is based on the shift from aerobic to anaerobic metabolism in underperfused tissues. This shift is marked by the production of lactate that can, in turn, be measured serially. Resuscitation of shock results in a decrease in serum lactate levels, and the time required to normalize serum lactate levels appears to be an important prognostic factor for survival.¹¹⁻¹⁵

Another biochemical marker useful in the resuscitation of shock is the base deficit. This is defined as the amount of a fixed base (or acid) that must be added to an aliquot of blood to restore the pH to 7.40. Base deficit values have been categorized as normal (2 to -2), mild (-3 to -5), moderate (-6 to -9), and severe (>-10). Changes in base deficit toward normal with volume infusion can be used to judge the efficacy of resuscitation.¹⁶⁻¹⁸ Base deficit has been shown to be superior to pH values in assessing the normalization of acidosis after shock resuscitation, and the time required for normalization of base deficit has perhaps even greater prognostic significance than that of lactate.^{16,19}

Table 9-1 Shock Recognition

Organ System	Sign/Symptom	Cause
CNS	Mental status changes (agitation/anxiety to coma)	Decreased cerebral perfusion
Circulatory		
Cardiac	Tachycardia Atrial/ventricular dysrhythmias Hypotension	Adrenergic stimulation Coronary ischemia Coronary ischemia, right heart failure
Systemic	Hypotension Decreased CVP Increased CVP	Decreased SVR, decreased venous return Hypovolemia Right heart failure
Respiratory	Tachypnea Cyanosis	Pulmonary edema, sepsis, compensation for metabolic acidosis Hypoxia
Renal	Oliguria	Decreased perfusion, afferent arteriolar vasoconstriction
Skin	Cool, clammy Warm, dry	Vasoconstriction Vasodilation

CNS, central nervous system; CVP, central venous pressure; SVR, systemic vascular resistance.

The biochemical changes associated with the hypoperfusion of shock occur even with compensation. Because of the potential difficulties in diagnosing compensated shock, an arterial and/or venous blood gas analysis including base deficit and lactate should be obtained for every patient suspected of being in shock. Additionally, any patient with a lactate of ≥ 4 mmol/L or base deficit of ≥ 6 mEq/L should be considered to be in shock until proven otherwise.^{17,20,21}

Future Measures: Although each of these factors can be used to characterize shock, no single measurement has been determined to be optimal or when used singly to be always accurate for identification and treatment of shock. Currently, other measurements are being investigated that demonstrate promise. These markers include measurements of central and mixed venous oxygen saturations, end-diastolic cardiac volume indices, and specific noninvasive end-organ tissue oxygen saturations.²²⁻²⁸

TYPES OF SHOCK

Although several different classifications for shock have been described, the most widely accepted classification of shock was proposed by Weil and Shubin in 1971.⁶ This classification divides the shock syndrome into four distinct categories (Table 9-2). Despite this separation, however, there is considerable overlap between the categories, with some patients presenting with more than one factor

at the same time. Given this overlap, it is helpful to evaluate the hemodynamic pattern in order to elucidate the etiology and manage the patient (Table 9-3).

Hypovolemic Shock

2 Hypovolemic shock is the form of shock most commonly encountered in surgical practice (Table 9-2). The essential feature is a reduction in intravascular volume to a level that prevents the heart from being able to pump sufficient blood to vital organ systems. Substantial blood (>20% circulating volume) or plasma (via soft tissue, enteric sequestration, gastrointestinal, urinary, or other insensible losses) losses are required to produce this syndrome.

The signs and symptoms of shock vary with both the severity and duration of fluid loss. A review of the Advanced Trauma Life Support classification system of the American College of Surgeons is useful to comprehend the manifestations and physiologic changes associated with hemorrhagic shock in adults.²⁹ Blood volume is estimated at 7% of ideal body weight, or approximately 4,900 mL in a 70-kg patient (Table 9-4).

Class I: Mild hemorrhage, up to 15% of total blood volume. This condition is exemplified by voluntary blood donation. In the supine position, there are no measurable changes in heart or respiratory rates, blood pressure, or pulse pressure. Capillary refill is normal. This degree of hemorrhage requires little or no treatment, and blood volume is restored within 24 hours by transcapillary refill and the other compensatory methods.

Class II: Loss of 15% to 30% of blood volume (800 to 1,500 mL). Clinical symptoms include tachycardia and tachypnea. The systolic blood pressure may be only slightly decreased, especially in the supine position, but the pulse pressure is narrowed (because of the diastolic increase from adrenergic discharge). Urine output is reduced only slightly (20 to 30 mL/hr). Mental status changes (e.g., anxiety) are frequently present. Capillary refill is usually delayed. Patients with class II hemorrhage usually can be resuscitated with crystalloid solutions, but some may require blood transfusion.

Class III: Loss of 30% to 40% of blood volume (up to 2,000 mL). Patients with class III hemorrhage present with inadequate perfusion that is obvious; marked tachycardia and tachypnea; cool, clammy extremities with significantly delayed capillary refill; hypotension; and significant changes in mental status (e.g., confusion, combativeness). Class III hemorrhage represents the smallest volume of blood loss that consistently produces a decrease in systolic blood pressure. The resuscitation of these patients frequently requires blood transfusion in addition to administration of crystalloids.

Class IV: Loss of more than 40% of blood volume (more than 2,000 mL), representing life-threatening hemorrhage. Symptoms include marked tachycardia, a significantly depressed systolic blood pressure, and narrowed pulse pressure or unobtainable diastolic pressure. The mental status is depressed and the skin is cold and pale. Urine output is negligible. These patients require immediate transfusion for resuscitation and frequently require immediate surgical or other (e.g., angiographic embolization) intervention.

In practice, individual susceptibility to blood loss varies greatly and is affected by age, pregnancy, pre-existing disease, prescription and nonprescription medications (e.g., beta blockers), adequacy of compensatory mechanisms, and other factors that are poorly characterized. Presence of these factors should lead the caregiver to consider early use of invasive monitoring as an adjunct to appropriate fluid resuscitation.

Hypovolemia due to plasma losses may also lead to hypovolemic shock. The clinical findings of hemorrhagic shock are typically present, but significant differences do exist. Hemoconcentration, elevated blood urea nitrogen (BUN) and creatinine, and hypernatremia are typical of acute plasma and/or free water losses and are not necessarily present in other forms of shock. Appropriate evaluation of preload and urine output should be followed, with specific considerations for unique electrolyte abnormalities associated with specific plasma and fluid losses (e.g., gastric vs. colonic losses).

Cardiogenic Shock

3 The clinical definition of cardiogenic shock is decreased cardiac output with tissue hypoperfusion, despite presence of adequate intravascular volume. It is caused by a primary problem with the cardiac muscle, electrical conduction system, or valves. The most common cause is anterior wall myocardial infarction, although in surgical patients it is often precipitated by pulmonary embolus, myocardial contusion, or pulmonary hypertension.

Distinguishing cardiogenic shock from other shock etiologies is occasionally difficult. It is not uncommon to see combined cardiogenic and traumatic shock in the elderly patient, with one often being

the precipitating event for the other. The hallmarks of the hemodynamic and neuroendocrine response to systemic hypoperfusion from other causes are also typical of cardiogenic shock. Eliciting a history of pre-existing cardiac disease, and physical findings such as pulmonary rales, cardiac murmurs, an S3 gallop, and jugular venous distention may be helpful. An electrocardiogram may detect significant ischemia or other pathology. A chest radiograph may reveal bilateral pulmonary infiltrates typical of cardiogenic edema, and cardio-specific serum tests (troponin I and creatine phosphokinase [CPK]) may indicate myocardial damage.

Manifestations of cardiogenic shock develop as a consequence of failure of peripheral perfusion, the associated adrenergic response, and the inability of the heart to accommodate blood returning from the lungs and the periphery. In the absence of sepsis or tissue injury, however, there is not usually an associated increase in the metabolic needs of the peripheral tissues. Sympathetic-mediated constriction of the peripheral vasculature attempts to maintain central blood pressure and perfusion of cerebral and coronary circulations. The clinical findings of cardiogenic shock may thus be similar to those of hypovolemic shock because both involve induction of the adrenosympathetic response.

Table 9-2 Classification System and Causes of Shock

Classification	Etiology	Cause
Hypovolemic	Hemorrhagic	Trauma Gastrointestinal
	Nonhemorrhagic	Absolute fluid loss (renal, gastrointestinal) Redistributive or “third spacing”
Cardiogenic	Myocardial	Ischemia Infarction Contusion Cardiomyopathy Myocarditis Pharmacologic/toxic (beta blockers, calcium channel blockers, tricyclic antidepressants, anthracycline) Metabolic (hypophosphatemia, hypocalcemia, acidosis)
	Valve failure	Infection Injury Ruptured papillary muscle Stenosis
	Arrhythmias	Ischemia Pharmacologic/toxic Metabolic
Extracardiac obstructive	Extrinsic compression Increased intrathoracic pressure Intrinsic vascular flow obstruction	Mediastinal tumors Tension pneumothorax Positive-pressure ventilation Pulmonary embolism Air embolism Tumors (myxoma) Proximal aortic dissection Aortic coarctation Acute pulmonary hypertension Tamponade Pericarditis
Distributive	SIRS related	Trauma Sepsis Pancreatitis Burns
	Anaphylactic/anaphylactoid	Drugs Venoms
	Neurogenic Toxic/pharmacologic	Spinal cord injury Vasodilators Benzodiazepines
	Endocrine	Adrenal insufficiency Thyroid Myxedema

SIRS, systemic inflammatory response syndrome.

Diminished or ineffective contractile activity of the right or left side of the heart allows blood to accumulate in the respective venous circulations. Shock from an acute left ventricular myocardial infarct

occurs when more than 40% of the left ventricle is involved and may be present in approximately 20% of Q-wave infarcts.³⁰ Shock from an acute right ventricular myocardial infarct, on the other hand, is rare and only occurs in approximately 10% of all inferior wall infarcts.³¹ Not only does the diagnosis of each infarct vary, but also the treatment and support vary significantly.

Table 9-3 Hemodynamic Patterns in Shock

Type	CO	SVR	PAOP	CVP	SvO ₂
Hypovolemic	↓	↑	↓	↓	↓
Cardiogenic					
Left ventricular MI	↓	↑	↑	N, ↑	↓
Right ventricular MI	↓	↑	N, ↓	↑	↓
Extracardiac obstructive					
Pericardial tamponade	↓	↑	↑	↑	↓
Pulmonary embolism	↓	↑	↑	↑	↓
Distributive					
Early	↑, N, ↓	↑, N, ↓	N	N, ↑	N, ↑
Early after fluid administration	↑	↓	N, ↑	N, ↑	↑, N, ↓
Late	↓	↑	N	N	↓

CO, cardiac output; CVP, central venous pressure; MI, myocardial infarction; N, normal; PAOP, pulmonary artery occlusion pressure; SvO₂, mixed venous oxygen saturation; SVR, systemic vascular resistance.

In any patient in shock, especially in those with compromised cardiac function, consideration should be given to the institution of mechanical ventilation. The work of breathing can be considerable, especially for the patient in a state of agitation or distress. Oxygen needs are decreased through intubation and mechanical ventilation. In this manner, the patient can be comfortably sedated with a secure airway; the work of breathing is undertaken by the ventilator, and gas exchange can be optimized. If there is a tenuous balance between myocardial oxygen needs and availability, the balance can thus be shifted in the patient’s favor.

Like other forms of shock, cardiogenic shock tends to be self-perpetuating. Myocardial perfusion depends on the pressure gradient between the coronary artery and the left ventricle and the duration of diastole. Both are compromised by the hypotension and tachycardia that characterizes this condition. High-volume fluid resuscitation, sometimes necessary for treatment of other forms of shock, is poorly tolerated and likely to be detrimental to an individual with the compromised myocardial function of cardiogenic shock.

Extracardiac Obstructive Shock

4 A subset of patients with cardiogenic shock do not have intrinsic cardiac disease but have pump failure due to extrinsic compression that limits diastolic filling and cardiac output. Cardiac tamponade, tension pneumothorax, diaphragmatic herniation of abdominal viscera, mediastinal hematoma, and, occasionally, positive-pressure mechanical ventilation may all precipitate cardiogenic shock by exerting constricting pressure on the myocardium. The key to diagnosis and appropriate therapy is the physical examination, supplemented by use of appropriate diagnostic modalities.

The classic physical findings of cardiac tamponade, Beck triad, are hypotension, muffled heart sounds, and jugular venous distention. Unfortunately, these nonspecific clinical findings are seldom present together. Elevated jugular venous pressure, noted by either physical examination or measurement of CVP, although not specific for cardiac compression, is usually present. Pulsus paradoxus can be useful for the diagnosis of cardiac tamponade. Although it may be caused by other conditions, it is virtually always present in patients with tamponade.

Given the difficulty in evaluation of these patients, especially in combination with other shock states, early diagnostic evaluation, both invasive and noninvasive, of cardiac function is warranted. Recent guidelines suggest that any patient with concern for primary or secondary cardiac dysfunction should undergo early ultrasound evaluation. This early evaluation not only evaluates the primary cardiac function but also can lead to the early diagnosis and management of secondary causes of cardiac dysfunction including cardiac tamponade and pulmonary embolism.

Table 9-4 Classification of Hemorrhagic Shock

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1,500	1,500–2,000	>2,000
Blood loss (%)	Up to 15	15–30	30–40	40
Heart rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35
Urine output (mL/hr)	>30	20–30	5–15	Minimal
Mental status	Normal	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

Table 9-5 Systemic Inflammatory Response Syndrome

Systemic inflammatory response syndrome: The systemic inflammatory response to a variety of severe clinical inflammatory factors is manifested by two or more of the following conditions:

Temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$

Heart rate >90 bpm

Respiratory rate >20 breaths/min or $\text{PaCO}_2 <32$ mm Hg

WBC count $>12,000$ cells/ mm^3 , $<4,000$ cells/ mm^3 , or $>10\%$ immature (band) forms

bpm, beats per minute; PaCO_2 , partial pressure of arterial carbon dioxide; WBC, white blood cell count.

Distributive Shock

Distributive shock occurs in a state of inappropriate oxygen utilization associated with the systemic inflammatory response syndrome (SIRS). Classically, SIRS is triggered by sepsis, but SIRS is associated with other immune processes including trauma, pancreatitis, and other types of tissue injuries. However, other types of distributive disturbances can occur unrelated to inflammation that may be directly due to loss of vascular tone from spinal cord injury, endocrine dysfunction, or anaphylaxis.

Septic Shock

5 Septic shock is defined as a SIRS response to infection in conjunction with arterial hypotension, despite adequate fluid resuscitation.³² It occurs when bacterial products interact with cells of the immune system, leading to elaboration of mediators that cause circulatory disturbances and direct and indirect cell damage leading to the clinical manifestations of SIRS (Table 9-5).³³ Hemodynamic changes are defined as early (warm or hyperdynamic) or late (cold or hypodynamic). These stages are primarily characterized by the degree of ventricular contractility and peripheral vasomotor impairment present, but can be misclassified if not appropriately evaluated. Early septic shock is distinguished by peripheral vasodilation, flushed and warm extremities, and a compensatory elevation in cardiac output. Although an increase in venous capacitance diminishes venous return to the heart, cardiac output is maintained via tachycardia and the decrease in afterload due to systemic vasodilation.

Late septic shock is characterized by impaired myocardial contractility due to local and systemic release of cardiac depressants, worsening peripheral perfusion, vasoconstriction, extremity mottling, oliguria, and hypotension. Peripheral oxygen utilization may be severely impaired by bacterial toxins, such as lipopolysaccharide (LPS) and the inflammatory products of the host's own immune response, resulting in metabolic dysfunction and acidosis despite a high systemic oxygen delivery. This inappropriate oxygen utilization and systemic shunting lead not only to confusion regarding the adequacy of resuscitation but also to progressive cell death. Together, both systemic hypoperfusion and the altered tissue metabolism create a vicious cycle that propagates the inflammatory response initiated in reaction to the initial infectious challenge leading to progressive cellular injury.

Due to both volume deficits and cardiovascular dysfunction, persistent perfusion deficits are common and contribute significantly to multiple organ failure and mortality. In fact, the fluid volume required for treatment may exceed that required for treatment of other forms of shock due to persistent microvascular endothelial capillary leak. As a result of this profound leak, interstitial and total-body fluid balances become extreme, leading to the potential development of marked hypoxia and the abdominal compartment syndrome (ACS).

Although appropriate early resuscitation and cardiovascular support are essential to the treatment of

septic shock, as important are early infection source control and appropriate administration of antimicrobials. In fact, numerous investigators have demonstrated that even a few hours delay in initiation of antimicrobial therapy is associated with a significant increase in mortality.³⁴

Traumatic Shock

The major contributor to shock after injury is hypovolemia due to hemorrhage. Even when hemorrhage ceases or is controlled, patients can continue to suffer loss of plasma volume into the interstitium of injured tissues and develop progressive hypovolemic shock. In addition, tissue injury evokes a broader pathophysiologic immunoinflammatory response and a potentially more devastating degree of shock than that produced by hypovolemia alone.

The degree to which direct tissue injury and an inflammatory response participate in the development and progression of traumatic shock distinguishes it from purely hypovolemic shock. Thus, traumatic shock results from direct tissue or bony injury, resulting in not only hypovolemia caused by fluid and blood loss but also an immunologic and neuroendocrine response to tissue destruction and devitalization. This combined insult complicates what might otherwise be straightforward hemorrhagic shock by inducing a systemic response that utilizes many of the inflammatory mediators present in septic shock.³⁵ These mediators propagate and intensify the effects of the initial hypovolemia and make subsequent multiple organ failure far more likely than occurs with hypovolemic shock alone.

Although this condition can lead to increased fluid requirements, common problems associated with this condition such as rhabdomyolysis should be aggressively evaluated and treated with optimal resuscitation.³⁶ In addition, common patient characteristics are known to alter traumatic shock resuscitation, in particular, morbid obesity that can result in delayed correction of metabolic acidosis and increased risk for organ dysfunction.³⁷

Thus, initial management of the seriously injured requires the assurance of an airway, breathing, and circulation; later management requires appropriate volume resuscitation and control of ongoing losses. Control of hemorrhage is a major concern and demands priority over attention to other injuries. After resuscitation and control of volume losses, efforts become necessary to minimize the potentially lethal postshock sequelae, including acute respiratory distress syndrome (ARDS) and multiple organ dysfunction syndrome (MODS).

Neurogenic Shock

Neurogenic shock is defined as failure of the nervous system to provide effective peripheral vascular resistance, resulting in inadequate end-organ perfusion. Warm, flushed, flaccid extremities; paraplegia; confusion; oliguria; and hypotension are the classic clinical findings. Injury to the proximal spinal cord, with interruption of the autonomic sympathetic vasomotor pathways, disrupts basal vasoconstrictor tone to peripheral veins and arterioles. Profound vasodilation of all microvascular beds below the level of cord injury diminishes venous return to the heart, reduces cardiac output, and precipitates hypotension. Injuries at or above the fourth thoracic vertebrae may disrupt sympathetic enervation to the heart, resulting in significant bradycardia and severe decompensation.

Similar to the initial therapy for shock resulting from hypovolemia, treatment of the relative hypovolemia due to vasodilation of neurogenic shock requires intravenous volume resuscitation. Restoration of the pathologically expanded intravascular space improves preload and cardiac output and may reverse hypotension. However, maintenance of adequate hemodynamics often requires vasopressor support in an effort to avoid the administration of excessive fluids. CVP monitoring to assess cardiac preload should be considered as a means of determining adequate and nonexcessive filling pressures, as loss of vasomotor capacity within the pulmonary circulation predisposes these patients to pulmonary edema. As spinal cord injury is often associated with other traumatic injuries, the diagnosis of isolated neurogenic shock must be a process of exclusion.

This condition should not be confused with spinal shock. Spinal shock is defined as a loss of sensation accompanied by motor paralysis with initial loss but gradual recovery of spinal reflexes following spinal cord injury. The reflexes caudal to the spinal cord injury are hyporeflexic or absent, while those rostral are unaffected. No circulatory compromise is associated with this condition; thus, it should not be considered a shock state.

Hypoadrenal Shock

The role of adrenocortical hormones in providing resistance to shock is well recognized. The reduction in effective blood volume and changes in blood chemistry that occur after adrenalectomy are similar to

those of shock and hemorrhage. Adrenalectomized animals have markedly diminished tolerance to both trauma and hypovolemia. Adrenal cortical hormones also play a key role in maintaining normal capillary tone and permeability. In recent years, the concept of functional or relative adrenal insufficiency has received increasing attention as a cause of unrecognized shock and hypoperfusion. Most critically ill patients have elevated cortisol levels, but some have low concentrations in relation to the degree of stress imposed by their disease. Administration of physiologic doses of steroids to correct this insufficiency may result in stabilization of hemodynamics and possible survival benefits.³⁸ However, the concept of routine administration of physiologic doses of steroids has been questioned; thus, routine and indiscriminate use is not recommended.³⁹

Diagnosis of hypoadrenal shock is difficult, as classic signs of Addison disease are absent. The only clinical clues may be unexplained hypotension and refractory response to high-dose vasopressors. An isolated serum cortisol level is difficult to interpret because the range of values observed in critically ill patients varies considerably. A cortisol level below 15 µg/dL suggests a high likelihood of adrenal insufficiency, whereas a value above 35 µg/dL suggests adequate adrenal function.⁴⁰ The adrenocorticotrophic hormone (ACTH) stimulation test may be used to identify hypoadrenal patients when the diagnosis is unclear, but the utility of this test, particularly with an elevated baseline value, is of questionable utility.

The utility of the ACTH stimulation test is especially questionable in patients with persistent evidence of shock and elevated baseline levels of cortisol above 35 µg/dL. These patients actually demonstrate evidence of inadequate systemic cortisol utilization with a significant risk of mortality, and thus may actually benefit from systemic administration of physiologic concentrations of corticosteroids.⁴¹

Although hypoadrenal shock may complicate various types of shock, there is conflicting evidence to support the use of supplemental corticosteroids in patients with septic shock if there is biochemical evidence of hypoadrenalism. Thus, supplemental corticosteroids should be used with extreme caution until further evidence is available.^{32,41}

Physiologic Response to Hypovolemia

Common to each shock state is usually an initial decrease in circulating intravascular volume. This reduction is due directly to fluid loss or secondarily to fluid redistribution. This reduction in circulating fluid volume initiates both a rapid and sustained compensatory response. Within minutes, a rapid compensatory response occurs primarily due to adrenergic output. Sustained responses, in contrast, occur slower and result in intravascular fluid reabsorption and renal conservation of water and electrolytes ([Algorithm 9-1](#)).

Rapid Response

Hypovolemia results in the initial secretion of epinephrine and norepinephrine from the adrenal gland due to decreased afferent impulses from arterial baroreceptors. Catecholamine release is acute and limited to the first 24 hours following the onset of hypovolemia. This results in vasoconstriction, tachycardia, and increased myocardial contractility. Adrenergic-induced vasoconstriction of the systemic capacitance of small veins and venules shifts blood back to the central venous circulation, thus increasing right-sided filling pressures. Left-sided filling and pressure are augmented by pulmonary vasoconstriction. Concomitantly, vasoconstriction occurs in the skin, kidneys, and viscera, effectively shunting blood to the heart and brain. Adrenergic-induced vasoconstriction increases cardiac filling and causes increased contractility and reflex tachycardia, all of which combine to increase stroke volume and cardiac output.

Algorithm 9-1

Algorithm 9-1. Neurohormonal response to hypovolemia. CNS, central nervous system; ACTH, adrenocorticotrophic hormone; AVP, arginine vasopressin.

Adrenergic-mediated vasoconstriction affects arterioles, pre- and postcapillary sphincters, and small veins and venules. Due to this specific vasoconstriction, decreased hydrostatic pressure distal to the precapillary sphincter occurs that leads to reabsorption of interstitial fluid (water, sodium [Na⁺], and chloride [Cl⁻]) into the vascular space. This functions to restore circulating blood volume and is known as transcapillary refill.⁴²

Sustained Response

Sustained compensatory responses include the release of vasoactive hormones and fluid shifts from the interstitium and the intracellular space to the intravascular compartment. Decreased renal blood flow, increased adrenergic activity, and compositional changes in tubular fluid lead to the secretion of renin from the juxtaglomerular complex. Renin results in increased formation and release of angiotensin I by the liver. Circulating angiotensin I is rapidly converted to angiotensin II by the lungs and is the most potent known arterial and arteriolar vasoconstrictor. Angiotensin II also stimulates the release of pituitary ACTH. Increased circulating levels of both angiotensin II and ACTH result in increased secretion of aldosterone. As a result, reabsorption of Na⁺ in the distal renal tubules in exchange for potassium (K⁺) and hydrogen ions occurs.

Additionally, due to hypovolemia and increased serum osmolarity, reduced stimulation of arterial baroreceptors occurs, leading to the release of arginine vasopressin (AVP), also known as antidiuretic hormone (ADH). This hormone not only functions as a potent vasoconstrictor but also causes increased reabsorption of water by increasing water permeability and passive Na⁺ transport in the distal renal tubule. The overall net effect of aldosterone and AVP is to decrease glomerular filtration and increase salt and water tubular reabsorption in an effort to replace circulating intravascular volume deficits.

Finally, the increased release of the stress hormones (epinephrine, ACTH, cortisol, and glucagon) leads to glycogenolysis, lipolysis, and protein catabolism, causing a negative nitrogen balance and high extracellular concentration of glucose due to decreased insulin release and resistance. This leads to increased glucose utilization by insulin-independent tissues such as the brain and heart. In addition to glucose, products of anaerobic metabolism from hypoperfused cells accumulate in the extracellular compartment, inducing hyperosmolarity. This extracellular hyperosmolarity draws water from the intracellular space, increasing interstitial osmotic pressure, which in turn drives water, Na⁺, and Cl⁻ across the capillary endothelium into the vascular space.

ORGAN-SPECIFIC COMPENSATORY RESPONSES TO SHOCK

Cardiac and Microvascular Response

Cardiovascular physiology is profoundly affected by shock (Table 9-3). Reduced stroke volume is caused by an absolute or relative loss of preload. Intrinsic neuroendocrine and renal compensatory responses, along with additional intravenous fluid, are needed to increase ventricular end-diastolic volume. Restoration of adequate preload alone is often sufficient to return cardiac output to levels required to overcome peripheral perfusion deficits. However, some cases are complicated by acquired myocardial contractility derangements. Contractile function under these conditions is less a function of preload and more related to intrinsic myocardial dysfunction.

A defining characteristic of shock is compromise of microvascular perfusion. Far from being a passive conduit, the microvasculature actively participates in the response to shock. Arteriolar vessels are innervated by sympathetic nerves, as are small veins and venules. The vasoconstriction of hypovolemic shock and the vasodilation of septic and neurogenic shock are a result of these autonomic responses. The majority of the circulating blood volume resides in the venous system, and normal physiologic compensation mechanisms rely on this venous blood pool as an autotransfusion reservoir. Collapse of underperfused veins passively propels blood toward the heart, while α -adrenergic venoconstriction actively mobilizes the venous pool. Profound peripheral vasoconstriction via α -adrenergic, vasopressin, angiotensin II, and endothelin-1 stimulation of arteriolar and precapillary smooth muscle sphincters selectively diminishes perfusion to dermal, renal, muscle, and, significantly, splanchnic vascular beds to preserve perfusion of critical central organs, primarily the central nervous system (CNS) and myocardium.⁴³

The capillary endothelial monolayer maintains a semipermeable barrier between the intra- and extraluminal spaces and is compromised by shock.⁴⁴ Circulating inflammatory mediators and byproducts of infection (LPS, thrombin, tumor necrosis factor alpha [TNF- α], interleukin [IL]-1, nitric oxide, and endothelin-1) generated in response to traumatic or septic shock have been shown to induce and sustain endothelial capillary leak. Although the exact mechanisms of endothelial monolayer dysfunction are unclear, the only available therapies to reverse microvascular decompensation are timely restoration of peripheral perfusion, rapid elimination of infectious and necrotic tissue, and pharmacologic and mechanical support of cardiopulmonary function.^{45–46}

Neuroendocrine Response

The neuroendocrine reaction to shock consists of involuntary responses by the hypothalamus, autonomic nervous system, and secretory endocrine glands and is directed toward restoration of tissue perfusion and a redirected utilization of metabolic substrates. The autonomic response is initially triggered by hypoxia, hypotension, or hypovolemia detected by aortic and carotid baroreceptors and chemoreceptors (Algorithm 9-2). Subsequently, sympathetic vasoconstriction of specific vascular beds, induced by direct synaptic release of norepinephrine, results in redistribution of circulating blood volume from tissue of low metabolic activity to more metabolically demanding organs. Cardiac output, diminished by loss of preload, is augmented by inhibition of cardiac vagal activity and a resulting reflex tachycardia.

Circulating epinephrine and norepinephrine alter several aspects of glucose utilization, availability, and metabolism. The hyperglycemia of stress results from catecholamine-induced glycogenolysis, gluconeogenesis, and decreased pancreatic insulin release. Simultaneously, hypothalamic stimulation of the anterior pituitary induces release of ACTH, which in turn prompts cortisol and aldosterone release by the adrenal cortex. Elevated serum cortisol contributes to postinjury hyperglycemia by increasing gluconeogenesis, enhancing lipolysis, and diminishing peripheral utilization of glucose and amino acids. The pancreatic response is characterized by a decrease in insulin release and an increase in glucagon secretion, which further stimulates hepatic gluconeogenesis. The combined actions of catecholamines, cortisol, and glucagon are synergistic and create a shock-related hyperglycemia that is often refractory to insulin treatment.

Renal juxtaglomerular secretion of renin in response to adrenergic stimulation and renal hypoperfusion triggers the formation of angiotensin I in the liver, which is subsequently converted to angiotensin II by the lungs. Angiotensin II, a potent vasoconstrictor, augments shock-induced catecholamine-mediated peripheral and splanchnic vasoconstriction and stimulates aldosterone release from the adrenal cortex. Renal tubular reabsorption of sodium in response to elevated circulating aldosterone creates highly concentrated, low-volume urine. Vasopressin secretion by the posterior pituitary similarly contributes to compensatory restoration and maintenance of intravascular volume by promoting water reabsorption by the renal distal tubules and by causing peripheral and splanchnic vasoconstriction. A major result is a prolonged severe hypoperfusion of the splanchnic vascular bed, further augmenting the deleterious host response.

Immunoinflammatory Response

Many shock-inducing events, particularly those associated with septic or traumatic shock, simultaneously trigger a massive systemic inflammatory response. Although inflammatory mediators (TNF- α , ILs, chemokines, etc.) play an integral role in the recovery of local tissue to trauma and infection, an uncontrolled systemic inflammatory response contributes to organ failure. Immunologically active cells involved in the systemic inflammatory response include nucleated blood cells (monocytes, polymorphonuclear leukocytes [PMNs]) and platelets, microvascular endothelial cells, and tissue macrophages. These cells generate and secrete scores of signal-amplifying inflammatory mediators ranging in complexity from individual molecules (nitric oxide) to large multisubunit, extensively modified proteins (TNF- α , IL-1, etc.). Even transient systemic elevation of any of these mediators has profound physiologic consequences.

Local tissue destruction, microbial contamination, and infection similarly activate the coagulation cascade and induce platelet aggregation and release of numerous platelet-, endothelial-, and clot-derived vasoactive mediators. Persistent, profound, and recurring microvascular hypoperfusion of the splanchnic and other organs likewise causes local tissue ischemia, parenchymal cell injury, microvascular coagulation, activation of inflammatory cells, and release of inflammatory mediators. Circulating monocyte, lymphocyte, and PMN adherence to activated endothelium results in extraluminal transmigration of these inflammatory cells into tissues remote from the area of injury. This hyperdynamic immunologic response, with continued generation of proinflammatory mediators, is responsible for the progression of SIRS toward MODS.^{47–50}

Regulation of the systemic inflammatory response has been an active area of shock research for several decades. Elimination of particular inflammatory mediators from the systemic circulation, or inhibition of particular cell–cell interactions in experimental animal systems, has been shown to improve outcomes after shock resuscitation.^{51–55} However, to date, all efforts to regulate the SIRS response with therapeutic elimination or supplementation of specific proinflammatory and anti-inflammatory mediators have proven ineffective or even harmful in humans. This lack of efficacy may relate to inadequacy of current animal models of shock, sepsis, and organ failure or to inadequate

understanding of the full spectrum and interactive nature of key elements that regulate this syndrome. Unfortunately, the network of inflammatory mediators and affected cells is so complex and redundant that no single agent is likely to be effective at interrupting this response. As a result, there is probably no single common pathway likely to respond to a “silver bullet” approach.

Pulmonary Response

The lung is the organ system most sensitive to systemic insult and injury and is frequently the first organ to fail in the progression to MODS. ARDS represents a high-mortality form of pulmonary insufficiency that is often precipitated by sepsis or traumatic shock. It is triggered and perpetuated by the numerous inflammatory mediators created in the hypoperfused microvasculature elsewhere in the body.^{51–56}

Interstitial edema and subsequent reduced compliance result in diminished tidal volume and tachypnea, compromising gas exchange. Surfactant abnormalities contribute to alveolar collapse, resulting in loss of functional residual capacity (FRC) and the onset of pulmonary insufficiency. The pulmonary microvascular response mirrors the systemic response, with angiotensin and α -adrenergic-induced vasoconstriction creating significant elevations of pulmonary vascular resistance, further straining the heart. Pulmonary parenchymal injury may be propagated by excessive positive-pressure ventilation generated by alveolar overdistention in particular, further contributing to alveolar damage.

No specific measures are available to reverse the ARDS process; therefore, aggressive management of predisposing conditions is most appropriate. Once ARDS has become fully developed, treatment involves intensive supportive care while minimizing iatrogenic insults. As a result, early utilization of lung-protective strategies may diminish progressive ventilator-induced lung injury and improve outcome.⁵⁷

Renal Response

Direct sympathetic-induced renal vasoconstriction increases afferent arteriole resistance in response to shock. This effect is reinforced by elevated circulating angiotensin II and catecholamines. The resulting decrease in renal blood flow and glomerular filtration rate (GFR), along with elevated circulating aldosterone and vasopressin (ADH), produce oliguria and prerenal azotemia. Acute tubular necrosis (ATN) may result from prolonged decreases in renal cortical blood flow, as well as from toxins generated during sepsis. Oliguric renal failure, like the pulmonary insufficiency of ARDS, is a common component of MODS.

Distinguishing low urine output due to oliguric renal failure from the oliguria of decreased renal perfusion pressure can be aided by analyzing urine sodium and osmolality. Renal hypoperfusion usually results in urine sodium of less than 20 mEq/L with an osmolality of greater than 400 mOsm/kg, whereas acute tubular injury impairs sodium reabsorption and is associated with a low urinary osmolality. A fractional excretion of sodium of less than 1% may also help determine whether the cause is renal or prerenal.

Early detection of abnormal kidney function is critical to prevent progression to renal injury. Abnormal renal function can be detected as a decline in creatinine clearance. The correlation between a creatinine clearance based on a 24-hour collection and a sample collected over a shorter interval is poor. However, the 24-hour value represents an average value over that time. A sample obtained over a shorter period may reflect the time in question and allow timely recognition and treatment of renal dysfunction.

Hepatic Response

Ischemic injury to liver is not apparent early during shock. However, the liver plays an important role in the regulation of shock and subsequent tissue injury through both the release of acute-phase reactants and lack of clearance of potential toxic agents. As shock continues, hepatic necrosis occurs, leading to the release of aspartate aminotransferase and alanine aminotransferase. Continued shock results in attenuated synthesis of coagulation factors, albumin and prealbumin. Although progressive ischemia can occur, leading to complete loss of glycogen stores and marked hypoglycemia, this condition is rare without pre-existing liver disease, significant direct liver injury, or hepatic artery occlusion.

Genetic Regulation of the Response to Shock

Individuals vary considerably in their susceptibility to shock and in their ability to recover from its consequences. Recently, unique host-specific responses have been identified as important determinants

of the outcome of sepsis and septic shock. Genetic predispositions in an individual's immunoinflammatory response may dictate whether infection is adequately or inadequately countered. These differences in response may be partially explained by single nucleotide polymorphisms (SNPs) in the genetic sequences for various inflammatory mediators. These subtle nucleotide variations may affect the transcription or translation of associated genes or the secretion or function of the corresponding proteins.

The recognition that genetic background may regulate the response to severe sepsis and septic shock has led to the identification of an array of genetic markers associated with enhanced risk of septic mortality. These SNPs are in genes encoding proteins involved in pathogen recognition (toll-like receptors 2, 4, and 5; CD14; and mannose-binding lectin), cytokine expression (TNF- α , IL-1, IL-6, and IL-10), and several other genes involved in mediating and controlling the innate immune response and the inflammatory cascade.^{58,59}

Investigation into genetic polymorphisms should provide important insights into the pathophysiology of shock. SNP identification leading to early diagnosis of individuals at risk of developing or dying from the complications of shock may allow therapies to become more preemptive and effectively targeted.

LOSS OF COMPENSATORY RESPONSES TO SHOCK

If shock is prolonged, the arteriolar and precapillary sphincters become refractory and relax, while the postcapillary sphincter remains in spasm. Therefore, the capillary hydrostatic pressure increases, and Na⁺, Cl⁻, and water are moved into the interstitium, leading to depletion of intravascular volume.

Cellular membrane function is also impaired with prolonged shock. The normal negative membrane potential approaches neutrality, leading to increased permeability and interstitial flooding by K⁺. This is caused, at least in part, by a decrease in the normal function of the adenosine triphosphate-dependent Na⁺-K⁺ membrane pump that is a result of cellular hypoxia. The loss of the membrane potential difference leads to cellular swelling due to an intracellular influx of Na⁺ and fluid.

In addition to these cellular effects, severe and prolonged shock results in the development of progressive organ dysfunction. Although the mechanisms responsible are incompletely understood, it appears that the vital organs, in particular the lung early on, are limited in their ability to protect themselves during shock. As a result, direct endothelial injury occurs, resulting in leakage of various inflammatory mediators, which in turn results in accumulation of interstitial fluid and subsequent reduction in nutrient and gaseous diffusion. This condition, along with progressive microcirculatory thrombosis, is responsible for the late organ dysfunction characteristic of uncompensated shock.

COMPLICATIONS OF SHOCK

Ischemia–Reperfusion Injury

Inadequate microvasculature flow results in activation of leukocytes and converts local endothelial cells to a proinflammatory, prothrombotic phenotype. On reperfusion, the reintroduction of oxygen prompts these cells to generate superoxide anion, hydroxyl radicals, and hydrogen peroxide, further injuring local tissue. Microvascular endothelial adherence, monolayer transmigration, and local oxidative burst by activated neutrophils, along with the profound loss of endothelial monolayer integrity (i.e., microvascular capillary leak), contribute to massive interstitial edema after reperfusion. Although all tissues are sensitive to varying degrees, ischemia–reperfusion injury appears to be most detrimental to the pulmonary vasculature and the splanchnic circulations. Pulmonary interstitial edema and alveolar fluid accumulation are associated with the development of ARDS, whereas extensive visceral edema may contribute to development of ACS and mesenteric ischemia.

Second-hit Phenomena

Patients who have been successfully resuscitated from shock are at risk for what is referred to as the second-hit phenomenon. A single episode of severe or prolonged shock may precipitate organ failure, but, in addition, the initial insult may “prime” the inflammatory response, resulting in an augmented or prolonged response to a subsequent insult such as an infection, a second episode of blood loss, or major surgery.⁶⁰ For example, after the primary event, circulating neutrophils demonstrate enhanced superoxide anion production, increased endothelial cell adherence, augmented cytokine response, and

increased cytotoxicity. Not only do circulating innate immune cells demonstrate this priming effect, but tissue-fixed cells, in particular the macrophage, demonstrate altered phagocytosis and augmented cytokine release.⁶¹ This dysfunctional response leads to not only diminished microbial clearance and enhanced risk of nosocomial infection but also increased host tissue injury and subsequent development of MODS.

Multiple Organ Dysfunction Syndrome

6 MODS rarely develops as a result of isolated cardiogenic or neurogenic shock but is most often precipitated by septic and traumatic shock complicated by second-hit events such as repeated episodes of hypovolemia, subsequent infection, or repeated blood transfusions. Similarly, the presence of an unresolved inflammatory focus (such as devitalized necrotic tissue), undrained bodily fluids, or unresolved regional perfusion deficits can be the primary causes for the persistence of SIRS and the transition to MODS.

The effects of shock, resuscitation, and reperfusion and the subsequent development of MODS appear to depend on changes in the splanchnic and pulmonary microcirculations. These vascular beds appear to be major sites of the activation and subsequent immunoinflammatory mediator production that is responsible for the SIRS response. As splanchnic microcirculatory flow decreases in response to homeostatic vasoconstrictive responses during hypovolemia, excessive and prolonged hypoperfusion of the gut results in extensive microvascular injury and subsequent activation of endothelium, neutrophils, and macrophages. In addition, mucosal barrier disruption permits translocation of bacteria and bacterial toxins to circulate and reach the large tissue-fixed macrophage population in the liver. Extensive activation of the Kupffer cells in the liver results in the release of inflammatory mediators that cause distant organ injury through the systemic activation of other immune cells.

Not only is a proinflammatory phase of SIRS present, but there is also a compensatory anti-inflammatory phase of the SIRS response that is evolutionarily designed to counter the locally generated hyperimmune response and check systemic spread of proinflammatory mediators. If the compensatory anti-inflammatory response syndrome (CARS) results in excessive immunosuppression, it may contribute to susceptibility to primary and secondary infections that can then lead to organ failure.⁶²

Numerous clinical trials utilizing proinflammatory and anti-inflammatory mediators as therapeutic interventions have been conducted. Unfortunately, few therapeutic agents designed to counter immune dysfunction have had significant impact on the prevention and treatment of MODS. Although studies are planned and undergoing, no study has demonstrated a sustained impact to date. Several potential targets, including interferon, have been suggested but this theoretical benefit may prove incorrect as so many other targets have in the past.⁶³

Abdominal Compartment Syndrome

ACS is a highly morbid complication of reperfusion injury to the splanchnic viscera. This syndrome appears to be increasingly prominent due to aggressive resuscitation techniques that enable salvage of profoundly hypotensive and hypovolemic patients. Splanchnic ischemia and reperfusion result in extensive visceral capillary leak and interstitial edema of the bowel. Excessive volume resuscitation during this phase leads to grossly edematous viscera within the closed space of the abdomen, which dramatically increases intra-abdominal pressure, and compromises intra-abdominal organ function, increases renovascular resistance, limits diaphragmatic excursion, and may decrease cardiac output and elevate intracranial pressure. The clinical hallmarks of ACS are a distended and tense abdomen, diminished tidal volume, pulmonary edema, decreased cardiac output, oliguria, and elevated urinary bladder pressure. Presence of all or a major part of this syndrome should prompt consideration of an urgent operative laparotomy to decompress the abdomen and treat by leaving the abdomen open.

Hypothermia

Hypothermia (core temperature $<35^{\circ}\text{C}$) is common during shock. In addition to immobilization, both prehospital and postadmission exposure can lead to conductive, convective, and evaporative heat loss, which should all be minimized. In addition, the administration of room temperature intravenous fluids and of cold-stored blood also contributes to hypothermia.⁶⁴ Hypothermia increases fluid requirements and independently increases acute mortality rates.⁶⁵

As the core temperature decreases, the rate of oxygen consumption also decreases, to approximately 50% of normal at 28°C . The decrease in oxygen consumption is accompanied by increased production of acid metabolites. A leftward shift in the oxyhemoglobin dissociation curve also occurs with hypothermia

but is partially compensated by the acidosis. CNS effects progress from confusion and loss of manual dexterity to obtundation and frank coma as the core temperature decreases from 35°C to 26.5°C. The heart rate decreases to approximately half of baseline at 28°C, with a concomitant decrease in cardiac output. All cardiac electrical conduction intervals are prolonged, consistent with the changes in heart rate, and both atrioventricular dissociation and refractory ventricular fibrillation occur at 28°C. Other potential physiologic effects include ileus and pancreatitis (from cold enzyme activation) at temperatures lower than 35°C.

Compensatory responses to hypothermia include increased excretion of catecholamines, resulting in doubling of the basal metabolic rate, and increased production of thyroid hormones, further increasing the basal metabolic rate to five times baseline. Shivering can increase heat production as well, but it represents a significant energy expenditure and has been shown to be inhibited during episodes of hypotension or hypoxemia.⁶⁶ Compensatory responses to hypothermia are lost at temperatures below 30°C or 31°C, and a state of complete poikilothermy is reached.

The treatment for hypothermia is rewarming. The core temperature should be obtained on admission of the trauma patient. Patients whose core temperatures are 33°C to 35°C can be treated with passive rewarming, warm blankets, and hot packs. Patients with core temperatures lower than 33°C require active rewarming. If the patient is unconscious, airway control should first be obtained. Because severe hypothermia causes vasoconstriction, noninvasive blood pressure measurements may not be feasible or accurate, and an arterial line should be placed for monitoring and blood gas sampling. The inspired gas through the ventilator should be heated to 41°C and fully saturated with water vapor to increase heat conductance in the lung. The intravenous fluids should also be warmed. Commercially available rapid infusion systems with countercurrent heating elements should be used. For extreme hypothermia, continuous mechanical arteriovenous rewarming can be performed for both circulatory support and rewarming. Recently developed microtechnology permits core rewarming by percutaneous placement of countercurrent warming coils directly in the inferior vena cava (IVC). Finally, other warming methods include lavage of heated saline through nasogastric and thoracostomy tubes as well as peritoneal lavage, but are not as effective.

Coagulopathy

Coagulopathy is a frequent problem complicating shock, especially in those patients who have received large volumes of crystalloid solution and blood for resuscitation. Although this problem is incompletely understood, it is clear that coagulation defects during shock are multifactorial. The presence of shock, the fluid volume required for resuscitation, the presence of hypothermia, and pre-existing diseases all influence the likelihood and severity of coagulopathy.⁶⁷

A major factor in coagulopathy is usually due to the dilutional thrombocytopenia that occurs after massive volume resuscitation. Although bleeding times can be prolonged with platelet counts less than 100,000 cells/mL, platelet counts of 50,000 cells/mL or greater are usually adequate for surgical hemostasis. Dilutional thrombocytopenia becomes more likely with infusions of more than one blood volume. Each unit of platelets administered increases the platelet count by 10,000 to 15,000 cells/mL. Control of surgically remediable hemorrhage is prudent before platelet transfusion to prevent the loss of the transfused platelets.

Dilution of other coagulation factors also plays a role in development of coagulopathy. Factors V and VIII are the most labile in banked blood, but levels of less than 10% of normal for factors VII, X, XI, XII, and XIII are all associated with abnormalities in hemostasis, as demonstrated by prolonged partial thromboplastin time and prothrombin time. Fresh-frozen plasma can be administered as a source of all the soluble coagulation factors. The administration of cryoprecipitate may be necessary as a concentrated source of factor VIII and fibrinogen, particularly if adequate hemostasis is not obtained with the use of fresh-frozen plasma. Recent support has emerged for the use of recombinant activated factor VIIa. Although developed initially for use in hemophiliacs who developed inhibitors to factor VIII, anecdotal evidence has suggested that recombinant activated factor VIIa may serve to quickly reverse hemorrhage-induced coagulopathy.⁶⁸ However, the use of factor VIIa is associated with significant complications including pulmonary embolism, myocardial infarction, and stroke and thus is no longer considered an optimal way to reverse hemorrhage-induced coagulopathy.⁶⁹ Other agents have demonstrated promise in rapidly reversing coagulopathy, such as tranexamic acid for massive hemorrhage-induced coagulopathy and prothrombin concentrates for rapid reversal of anticoagulants.⁷⁰⁻⁷¹

Finally, evidence has suggested that coagulopathy and hemorrhage can be minimized following

massive blood loss if early aggressive use of fresh-frozen plasma is administered. Military data demonstrate that significant early coagulopathy is present after massive injury, even before blood component therapy is begun. Both civilian and military experience with a 1:1 ratio of packed red blood cells to fresh-frozen plasma has been associated with reduced mortality.⁷²⁻⁷⁴ However, this practice has been associated with an increase in the development of ARDS and organ dysfunction due to poorly defined mechanisms.⁷⁵ Thus, generalization of this data to all patients with hemorrhage other than the massively injured should be performed with caution as demonstrated in the PROPRR study.⁷⁶

TREATMENT

Fluid Therapy

Early investigators of hemorrhagic shock noted that decreased CVP and a reduction in total-body oxygen delivery (DO_2) were key early findings. If the decrease in oxygen delivery was severe or prolonged, a reduction in total-body oxygen consumption ensued. After adequate fluid resuscitation, oxygen delivery and consumption increased above the baseline value for several hours, as if the body was paying back an “oxygen debt.” Failure of the patient to achieve this hyperdynamic response to resuscitation was almost always fatal. Because early death from shock appeared to be explained by the dynamics of oxygen delivery and utilization, therapy focused on restoring hemodynamics and oxygen transport with fluid and inotropes.

The provision of additional fluid beyond the amount of blood loss was associated with improved survival in both clinical and experimental studies of hemorrhagic shock, leading to widespread acceptance of aggressive fluid infusion. However, some researchers have recently described a significant increase in mortality associated with crystalloid overresuscitation and have postulated that excessive fluid administration increases the clinical risk of ARDS, MODS, increased intracranial pressure, and ACS.⁷⁷⁻⁷⁹ Because massive volumes of fluid are only provided to patients with severe shock, it is unclear if it is the excessive fluid or the associated underlying shock that increases the risk of ARDS, organ failure, or death after massive fluid resuscitation.

A minimum of two large-bore (14- to 16-gauge) intravenous catheters should be established in adults. Isotonic fluid is then infused at the same time as blood is obtained for arterial blood gas analysis, screening, and typing. Fluid can be infused up to 200 mL/min through a 14-gauge catheter and up to 220 mL/min through a 7-French catheter. A fluid challenge of 10 to 25 mL/kg is administered to the hypotensive patient and the response is assessed (i.e., 2,000 mL or 40% of blood volume of a 70-kg man). This therapeutic challenge is an effective trial in determining the amount of pre-existing or continuing volume loss. If the blood pressure returns to normal and is stabilized, the volume loss was relatively small, and the only treatment required may be infusion of isotonic fluid.

If the increase in blood pressure is transient after fluid bolus, then hemorrhage or continued fluid losses are severe and ongoing. Additional crystalloid is administered, and the need for blood transfusion is assessed. Patients who continue to require large amounts of fluid and blood to support perfusion usually have ongoing hemorrhage and require surgical intervention. No response or a minimal response to apparently adequate infusions of crystalloid solution and blood indicates exsanguinating hemorrhage and the need for urgent surgery.

Crystalloids

Balanced salt solutions are the most commonly used resuscitative fluids, and their use to restore extracellular volume significantly decreases the transfusion requirement after hemorrhagic shock. Lactated Ringer solution is isotonic, readily available, and inexpensive. It rapidly replaces the depleted interstitial fluid compartment and does not aggravate any pre-existing electrolyte abnormalities. Previous investigations have shown that administration of lactated Ringer solution does not lead to aggravation of the lactic acidosis that is present in shock.⁸⁰ In fact, animal models have demonstrated that the use of blood plus lactated Ringer solution results in a more rapid return to normal lactate and pH than dose-shed blood alone. As volume and perfusion are restored, lactate is mobilized and metabolized to bicarbonate in a single pass through the liver. In fact, mild metabolic alkalosis may occur 1 or 2 days after large-volume resuscitations with lactated Ringer solution. Normal saline solution is also effective for resuscitation of hypovolemic patients. Concerns about inducing hypernatremic, hyperchloremic metabolic acidosis with massive resuscitation volumes remain but appear of less relevance by further investigation with normal saline and the hypertonic saline solutions.

Recently several investigations have raised concerns about the proinflammatory effects of resuscitation with lactated Ringer solution. Some commercially available lactated Ringer solutions contain racemic lactate that is made of equal concentrations of D(–)- and L(–)-isomers of lactate. The D(–)-isomer has been demonstrated in vitro to result in enhanced production of reactive oxygen species by neutrophils and inflammatory gene expression by leukocytes.^{81–82} In addition, increased apoptosis in both the small intestine and the liver was seen after resuscitation from hemorrhage with lactated Ringer solution but not with hypertonic solutions or blood resuscitation.⁸³ These findings, however, are not consistent and do not appear dissimilar from saline resuscitation in other animal models.⁸⁴ Thus, further investigations are required to determine the overall inflammatory effect of crystalloid resuscitation and extent of D(–)-isomer use in current commercial fluids.

Colloids

Colloids have the theoretic advantages of increasing the colloid oncotic pressure and requiring smaller volumes for resuscitation than crystalloids.⁸⁵ Colloids commonly used for volume expansion in hypovolemia include albumin, dextran 70, dextran 40, and hydroxyethyl starch. Although each has unique individual characteristics, currently there is little justification for the routine addition of colloids to balanced salt solutions for volume replacement during shock. In fact routine use of colloid such as hydroxyethyl starch may be associated with increased risk of mortality without any benefit.⁸⁶

Albumin solutions have been used during resuscitation to increase colloid oncotic pressure and, hypothetically, to protect the lung from interstitial edema; however, there is a relatively rapid flux of albumin across the pulmonary capillary membranes and relatively rapid clearance through the pulmonary lymphatics. In fact, colloid albumin infusion has been demonstrated to prolong the resuscitation phase and delay postresuscitation diuresis. Additionally, albumin may serve to depress circulating immunoglobulin levels and suppress albumin synthesis.

Dextran 40 and dextran 70 are polysaccharides with molecular weights of 40 and 70 kD, respectively. Dextran 40 (10%) is hyperoncotic and initially exerts a volume-expanding effect. However, because of its lower molecular weight, it is more rapidly excreted. Thus, dextran 40 is commonly used in cases of peripheral vascular disease and hyperviscosity syndromes. Dextran 70, conversely, is provided as a 6% solution and does not exert a hyperoncotic effect. The volume expansion is somewhat greater than the amount infused, and because of its large molecular size the effect is maintained for up to 48 hours. The dextran preparations, however, cause decreased platelet adhesiveness and decreased factor VIII activity. They also carry an incidence of allergic reaction of up to 5% and anaphylaxis of 0.6%.^{85,87}

Hydroxyethyl starch is an amylopectin with volume-expanding effects for approximately 36 hours. It has side effects similar to those of dextran, but with less frequency. The incidence of anaphylaxis is 0.006%. A new hydroxyethyl starch, pentastarch, has a lower molecular weight and fewer hydroxyethyl groups than hydroxyethyl starch. Pentastarch has a shorter duration of action (2.5 hours) and has been reported to have even fewer side effects.^{87–88}

The controversy regarding use of crystalloids versus colloids in resuscitation has not been resolved. Both types of solutions can restore circulating volume. The effects of the solutions on pulmonary function are at issue and are summarized as follows: (a) the use of crystalloid solutions decreases plasma oncotic pressure, thereby leading to lung edema at lower microvascular pressures; and (b) colloids given in the face of pulmonary injury can extravasate, promoting edema because of the reduced plasma interstitial oncotic gradient. In fact, a previous meta-analysis of colloid versus crystalloid resuscitation after hemorrhagic shock demonstrated a higher mortality rate among the colloid-resuscitated patients, partly because of pulmonary complications.⁸⁹ Therefore, since colloid infusion has not demonstrated a significant benefit over crystalloid resuscitation alone, it is not currently recommended in the management of hypovolemic shock.^{90–91}

Resuscitative Strategy

7 Aggressive fluid resuscitation is clearly a lifesaving modality and a key strategy in the treatment of shock and prevention of secondary consequences ([Algorithm 9-2](#)). However, indiscriminate fluid loading causes problematic edema in the lungs, gut, brain, and other organs. The amount of fluid used for resuscitation should be titrated to carefully selected hemodynamic and oxygen transport endpoints. Solutions currently in development (“artificial blood”) with oxygen transport capabilities may hold the potential of restoring oxygen transport while minimizing the need for large volumes.

Permissive Hypotension

Elevation of systemic arterial pressure in patients with disruption of the arterial system or major solid organ injury, especially after penetrating trauma, may cause acceleration of hemorrhage, disrupt natural clotting mechanisms, and cause dilution of clotting factors. Laboratory and clinical evidence support judicious use of intravenous fluids until hemorrhage is controlled by surgery, angiography, or direct pressure for penetrating trauma.⁹² Fluid resuscitation for patients with multisystem blunt trauma, especially with concomitant traumatic brain injury, represents a more complicated decision process, as maintaining cerebral perfusion pressure is a competing priority. Avoidance of both excessive fluid administration and prolonged hypoperfusion is best achieved in all patients not by maintenance of a marginal blood pressure, but by rapid surgical or angiographic intervention to control bleeding.

Transfusion

Anemia prompts clinical concerns because it may signify blood loss or hematologic disease, but it rarely causes tissue ischemia. The hemoglobin level that causes concern should depend on the adequacy of other mechanisms involved in oxygen delivery such as arterial oxygen saturation and cardiac output, the specific clinical situation, and the organ systems most at risk, balanced against the risk of transfusion. Clinical evidence suggests that hemoglobin values above 7 mg/dL are adequate in most patients, including the critically ill, but this has not been explored during shock. In one prospective randomized trial in critically ill patients, it was clearly demonstrated that a reduction in complications and improvement in survival were noted when lower hemoglobin values were accepted.⁹³ However, this study excluded patients with hypovolemia, acute coronary syndrome, and sepsis. Although the role of transfusion during shock remains problematic, it appears in patients without shock these thresholds of transfusion are even acceptable for elderly patients with significant cardiac disease.⁹⁴

Table 9-6 Comparison of Blood Availability

Blood	Typing	Antibody Screen	Cross Match	Time
Type O	No	No	No	Immediate
Type specific	Yes	No	No	<10 min
Type and screen	Yes	Yes	Yes	20–30 min
Type and cross match	Yes	Yes	Yes	45–60 min

Given this limitation, currently it is held that most patients with class I or II shock can be resuscitated with balanced salt solutions alone. Patients who lose more than 25% to 30% of total blood volume require blood for resuscitation, as do patients with persistent evidence of inadequate end-organ perfusion.²⁰ The decision about the extent of blood cross match prior to being transfused is determined in part by the urgency of the situation. Blood that has been fully typed and cross matched carries the least risk of transfusion reactions, but it also takes the most time to obtain. Other transfusion options include the use of type O or type-specific blood (Table 9-6).

Type O Blood

Type O (universal donor) blood is immediately available without a cross match. Because type O blood contains no AB cellular antigens, administration of packed red blood cells is relatively safe in patients with any blood type. Males should be transfused type O Rh-positive blood, while prepubescent females and females of childbearing age should be given type O Rh-negative blood to avoid sensitization that would complicate future pregnancies. The administration of more than 4 units of type O blood to a non-O-blood-type patient, however, theoretically can result in an admixture of blood type. A pretransfusion blood specimen should be sent to the blood bank when the patient is admitted, and type-specific blood should be transfused as soon as it is available.

Type-Specific Blood

Type-specific blood is available from most blood banks within 5 to 10 minutes of receipt of the blood specimen, while the patient is being resuscitated with balanced salt solutions. Although not cross matched, this blood can be administered safely, as demonstrated in both military and civilian experiences.⁹⁵

Autotransfusion

Autotransfusion involves collection of the shed blood and its reinfusion through a filter back into the patient. Autotransfusion can be as simple as aspiration of the blood into a citrate-containing collection

chamber, followed by reinfusion through a 40-mm filter. A more elaborate system, the Haemonetics autotransfuser (Haemonetics Corp., Braintree, MA), centrifuges the collected blood and delivers washed, packed red blood cells for reinfusion. The advantages of autotransfusion include transfusion with warm, compatible blood without delays and with no risk of transmission of hepatitis, human immunodeficiency virus, or other bloodborne pathogens.

Autotransfused blood can produce disseminated intravascular coagulation and activation of fibrinolysis. In addition, collection of blood from the peritoneal cavity after hollow viscus injury, even with cell washing, may lead to bacterial contamination of the autotransfused blood.⁹⁶ Successful autotransfusion of contaminated blood has been demonstrated, but blood obtained from enteric-contaminated cavities probably should not be used, except perhaps in extreme circumstances.⁹⁷ Despite the potential benefits, investigators have found that the autotransfuser was used in only 26% of the trauma patients for whom it was prepared.⁹⁸ Currently, no evidence exists that autotransfusion improves outcome compared to exclusive homologous blood transfusions in trauma patients.

Endpoints of Resuscitation

Endpoints of resuscitation can be categorized as either global or regional indicators of perfusion. Blood pressure and pulse are global measures and are relatively poor determinants of the adequacy of tissue oxygenation. They must also be interpreted in the context of patient age and pre-existing medical conditions. Tachycardia is a component of SIRS and does not always resolve with increased preload. Arterial pressure is maintained by myriad compensatory mechanisms, even in the face of a significant volume deficit, and interpretation is complicated by highly variable baseline pressures, age, and pre-existing medical conditions.

Base deficit and serum lactate are also global indicators of perfusion and may help in the detection of patients who are in otherwise compensated shock. Acidosis arising from regional tissues may not be apparent in peripheral blood samples, as is frequently the case in patients with intestinal ischemia, in whom systemic acidosis is a late finding. An elevated base deficit and lactate can be caused by electrolyte abnormalities, accelerated glycolysis or pyruvate production, and/or decreased clearance by the liver. They may also reflect dysfunction caused by a period of hypoperfusion that has already resolved and that does not need further treatment. A positive response toward correction, however, is indicative of appropriate resuscitation.

A PAC has obvious appeal as a monitor because ensuring adequate oxygen delivery is paramount in the treatment of shock ([Algorithm 9-2](#)). A progressive decline in systemic oxygen delivery (DO_2) results in an increase in the oxygen extraction ratio, evident as a reduction in pulmonary mixed venous oxygen saturation. When DO_2 is reduced below the level needed to maintain normal tissue metabolic activity, anaerobic metabolism occurs. This is evident as a decrease in total-body oxygen consumption (VO_2). Adequate resuscitation requires eliminating any pathologic decrease in VO_2 by restoring oxygen delivery to an adequate level. In clinical practice, however, there is no precise level of VO_2 that can be used as an endpoint, as tissue oxygen needs vary according to the patient's condition, level of sedation, body temperature, and other factors, and are affected by endogenous and exogenously administered catecholamines.

Oxygen consumption may be especially difficult to interpret in patients with late-stage sepsis because acquired defects in mitochondrial respiration may prevent utilization of oxygen, resulting in decreased consumption and progressive acidosis despite normal or high DO_2 .

The adequacy of resuscitation can also be assessed by measurement of end-organ function and perfusion, in addition to global measures. Blood flow to the most vital organs (brain and heart) is preserved during shock at the expense of flow to the skin, muscles, gut, and, ultimately, kidneys. Detection of ischemia in less vital organs could theoretically identify patients in compensated shock who have otherwise normal global indicators.

Low urine output (<0.5 to 1.0 mL/kg/hr) is an indicator of inadequate end-organ perfusion, but inappropriate urine output may initially be maintained by peripheral venoconstriction and maintenance of cardiac output due to tachycardia. The use of gastric tonometry to measure intramucosal pH has highlighted the uneven recovery from shock by visceral organs. Persistent visceral hypoperfusion, as demonstrated by intramucosal acidosis despite correction to normal hemodynamics, is associated with organ failure and poor outcomes. Unfortunately, direct measurement of visceral hypoperfusion, as well as hypoperfusion in other regional vascular beds, requires use of technically challenging, labor-intensive devices that often produce variable unreliable results and has not yet had widespread application. Presently, the goal of therapy is to restore tissue perfusion, both global and regional as measured by

organ function, and to normalize cellular metabolism while avoiding excessive use of fluids and inotropes.

Recently, several biomarkers, in addition to base deficit and lactate, have demonstrated potential promise. Among the most promising is procalcitonin for the early recognition of sepsis. However, in addition to being significantly elevated during sepsis, procalcitonin has recently been demonstrated, similar to lactate and base deficit, to be prognostic of outcome from hypovolemia based on rate of clearance.⁹⁹ Thus, this biomarker along with potential others may lead to early recognition and treatment of shock.

MONITORS

Central Venous Pressure

CVP has been used as a surrogate for venous return to the right heart and extended to represent preload. Preload is often diminished in the setting of shock and must be optimized in order to maintain adequate oxygen delivery. The venous system serves a capacitance function containing roughly two-thirds of our circulating blood volume. It is a compliant system that, in a healthy state, functions to maintain adequate venous return to the heart over a variable total blood volume. In states of shock, this capacitance function may be overcome by too low a circulating volume – as in the setting of hypovolemic or hemorrhagic shock – or by dysregulation – as in the setting of neurogenic or septic shock. CVP may be measured directly via an appropriately positioned central venous catheter. The catheter tip should ideally be positioned at the cavoatrial junction – roughly 2 cm caudal to the carina on chest x-ray.¹⁰⁰ Intravenous fluids are administered to achieve adequate preload. Despite challenges for the ability for CVP to determine preload, CVP still remains used clinically.¹⁰¹ In the surviving sepsis campaign, CVP is pushed to a goal of 8 to 12 mm Hg, which is thought to optimize preload.²⁰ This however, has been called into question in recent years with several investigators suggesting that there is no survival benefit to achieving such high CVPs.²⁰ It has certainly been demonstrated that CVP is not a perfect measure of venous return to the right heart or cardiac preload as there are several intrinsic cardiopulmonary factors that influence both CVP and cardiac output. The role of CVP may be most useful at its extremes and when used within the context of the patients' clinical situations. A CVP <5 mm Hg in the setting of a young, otherwise healthy trauma patient with ongoing hemorrhage is likely consistent with hypovolemic shock and warrants volume resuscitation. Alternatively, a CVP of 15 mm Hg in an elderly patient with known congestive heart failure does not alone provide adequate information as to a patient's volume status nor should it guide resuscitation. As such, CVP is one measure that can help to guide shock resuscitation when evaluated in the proper context.

Pulmonary Artery Catheter

Hemodynamic monitoring utilizing a flow-directed PAC has been a standard in the treatment of shock for decades and has been considered to be essential for optimal management of certain forms of shock. However, as a result of a multicenter study that reported that use of a PAC was associated with increased mortality, the indications for PAC use have recently been questioned.¹⁰² PAC patients were retrospectively compared to matched control patients who were selected using a scoring system. This scoring system has not been validated, which raises the possibility that physicians inserted a PAC in the more critically ill patients.

Intensive care unit (ICU) staffing practices may have also been a factor explaining these surprising results. The study was conducted in “open” ICUs, where any physician on the medical staff could admit a patient to the unit and insert a PAC. Clinicians may not always interpret PAC data appropriately. In a multicenter study of physicians' knowledge and interpretation of PAC data, nearly half (47%) were unable to appropriately determine the wedge pressure from a clear tracing, and a similar percentage (44%) could not identify the determinants of oxygen delivery.¹⁰³ Studies have demonstrated improved outcome when patients are managed in ICUs staffed by specialists in critical care, despite their more frequent use of PACs.¹⁰⁴

An additional consideration regarding the controversy over the utility of PACs is that currently used endpoints for PAC-guided resuscitation may be inappropriate. For example, efforts to augment systemic oxygen delivery have not demonstrated any benefits and, in fact, harm may be caused by this approach, whereas treatments used to alter the variables ascertained with the catheter may themselves cause harm (fluid overload, excessive inotropes, blood transfusions). Finally, PACs are associated with specific

complications, including the risk of central venous catheter insertion, endocarditis, and pulmonary artery injury, which may outweigh any potential benefits. As the safety and utility of the PAC have not yet been evaluated with prospective clinical trials in specific shock states, its usefulness in the management of shock remains to be determined.

Newer versions of the PAC have been developed that provide additional hemodynamic information, including continuous determination of cardiac output, ejection fraction, and calculated right ventricular end-diastolic volume. The pulmonary artery wedge pressure is a proxy for preload. However, the amount of precontractile stretch achieved with any given wedge or chamber pressure is modulated by the compliance of the ventricle. Therefore, cardiac chamber pressure may not be an accurate indicator of ventricular end-diastolic volume, just as end-diastolic volume may not be an accurate indicator of pulmonary wedge pressure and/or risk of pulmonary edema. The combination of both wedge pressure and end-diastolic volume may be optimal to maximize preload while avoiding excessive pulmonary capillary pressure. The use, however, has been mainly supplanted with the use arterial wave contour analysis and echocardiography.

A comparison of the pH and partial pressure of carbon dioxide (PCO₂) of mixed venous blood with a matched arterial blood sample can provide evidence of shock with tissue hypoxia. Hypoxic cells generate a hydrogen ion that is buffered by bicarbonate, resulting in increased production of H₂O and CO₂. An increase in venous PCO₂ results in an abnormal gap between mixed venous and arterial PCO₂ and pH and is a sign of anaerobic metabolism. With cessation of hydrogen ion production, this abnormal gap is quickly eliminated, whereas base deficit and hyperlactatemia may persist for several hours.

Arterial Wave Contour Analysis

Analysis of the arterial wave contour in a mechanically ventilated patient has been shown to be a marker of fluid responsiveness. This is a dynamic measurement, and as such, provides more information than static measures such as CVP or PCWP. Inspiration during positive pressure ventilation increases intrathoracic pressure and decreases venous return to the right heart. This, in turn, leads to a decrease in left ventricular preload, a lower stroke volume, and a decreased cardiac output. This effect is more pronounced in the hypovolemic patient, and calculation of PPV has been consistently shown to predict fluid responsiveness in critically ill patients. PPV is a measure of percent-change in the pulse pressure over the respiratory cycle, with a PPV greater than 12.5% being consistent with fluid responsiveness.¹⁰¹ Arterial wave contour analysis relies on patients having a sinus rhythm, no spontaneous respiratory function, and a tidal volume of at least 8 mL/kg. Interpretation of PPV and other arterial wave contour measurements should be cautioned outside of these parameters.

Bedside Ultrasound and Echocardiography

Improved ultrasound technology – better image quality and improved portability – over the past several years has led to its frequent use in the emergency department and intensive care settings. Ultrasound offers the benefits of being noninvasive, real-time, accurate, and reproducible. A focused cardiac ultrasound can provide information on both left and right ventricular function as well as volume status. Additionally, a pericardial effusion is easily identified and may be leading to tamponade physiology. Valvular disease is much more difficult to identify and may require a formal transthoracic or transesophageal echo.¹⁰⁵

In addition to assessment of cardiac function, ultrasound has demonstrated use in assessment of volume status and fluid responsiveness in shock states. Measurement of the superior vena cava (SVC), IVC, and left ventricular stroke area (LVSA) have proved helpful in guiding resuscitation. Measurement of the SVC and LVSA are performed via transesophageal echocardiography, which limits their routine use in patient management. However, SVC and LVSA variation over the respiratory cycle has been demonstrated to be predictive of fluid responsiveness.^{106–107} Measurement of the IVC is performed using bedside ultrasound. The IVC is identified just caudal to the diaphragm, and an anterior–posterior dimension is recorded at the end of expiration. In the setting of trauma and shock, an IVC diameter of <1 cm is consistent with a transient responder and correlates with fluid responsiveness.^{108,109} The use of ultrasound in critical care settings is growing and will continue to do so as technology and provider experience improves.

PHARMACEUTICAL SUPPORT

Therapeutic adjustments of preload and afterload form the basis of treatment strategies in all forms of shock. Optimal volume resuscitation should always precede measures to augment the contractile function of the heart. Inotropic augmentation of cardiac output may, therefore, be required when restoration of venous preload fails to provide sufficient cardiac output to satisfy tissue oxygen demands. The effect of inotropic agents depends on the specific adrenergic receptor affinity, chronotropic effects, and demands placed on myocardial oxygen consumption of the individual agents (Table 9-7). Vasodilators reduce demands on the myocardium and augment cardiac function via reduction in systemic vascular resistance (SVR) or afterload or by dilating the venous system and reducing cardiac preload. Afterload reduction may preserve stroke volume in the face of a failing myocardium, whereas venodilation reduces pulmonary capillary wedge pressure and pressure-driven pulmonary edema. Agents that increase afterload may be needed when blood pressure falls below the autoregulatory range of the coronary, cerebral, and renal vascular beds.

Inotropes and Vasopressors

Dopamine

Dopamine is an endogenous sympathetic amine that is a biosynthetic precursor of epinephrine and functions as a central and peripheral neurotransmitter. The effects of dopamine vary from individual to individual, and are altered with increasing doses. The highest-affinity receptors are occupied at low-serum concentrations (infusions <2 to 3 µg/kg/min) and consist of dopaminergic receptors in the renal and splanchnic beds that serve to augment regional blood flow, increase urine output, and cause natriuresis. However, multiple studies, including prospective randomized trials, have failed to demonstrate that low-dose dopamine prevents acute renal failure or decreases the need for dialysis in critically ill patients. At modest concentrations (3 to 5 µg/kg/min), dopamine occupies cardiac β₁-adrenergic receptors and increases myocardial contractility and heart rate. Higher doses (>5 µg/kg/min) cause an increase in heart rate and blood pressure. α-Adrenergic receptors are stimulated at higher-dose ranges (>10 µg/kg/min), resulting in elevation of blood pressure and peripheral vascular resistance. Dopamine is, therefore, an effective agent for increasing blood pressure in hypotensive patients after appropriate fluid resuscitation. Because the relationship among a specific dose, receptor affinity, and clinical effect is unique to each patient, individual titration is required to achieve the desired effect.

Table 9-7 Pharmacodynamics of Inotropic/Vasoconstrictor Agents

Drug	Metabolism	Sites of Action				Hemodynamic Response			
		Heart β ₁	Heart β ₂	Vessels α	Vessels β ₂	Renal Perfusion	CO	SVR	BP
Isoproterenol 1 mg/250 mL 1–2 µg/min initially	Renal	+++	+++	0	+++	+/-		–	+/-
Dobutamine 250 mg/250 mL 3 µg/kg/min initially	Hepatic	+++	0/+	0/+	0/+			–	0/+
Dopamine 200 mg/250 mL 2–5 µg/kg/min low dose 20–50 µg/kg/min high dose	Hepatic	+++	+	0	Low dose High dose		Low dose High dose	0/+	
Epinephrine 2 mg/250 mL 2 µg/min initially	Renal	+++	+++	+++	++	–		–	
Norepinephrine 4 mg/250 mL 4 µg/min initially	Renal	++	++	+++	0	–	+/-		
Phenylephrine	Renal	0	0	+++	0	–	–		

α (alpha), vasoconstrict peripheral arterioles; β₁ (beta-1) myocardial inotropy, chronotropy, enhance atrioventricular conduction; β₂ (beta-2) chronotropy, vasodilate mesenteric/skeletal bed, bronchodilation; dopaminergic, vasodilate mesenteric/renal bed. BP, blood pressure; CO, cardiac output; SVR, systemic vascular resistance.

Dobutamine

Dobutamine, a synthetic catecholamine, has a predominant affinity for β-adrenergic receptors. At clinically relevant doses (5 to 20 µg/kg/min), dobutamine enhances myocardial contractility with mild

to moderate changes in heart rate. It also induces peripheral vasodilation, which limits its utility in patients with hypotension. It is an appropriate agent when cardiac output augmentation, not blood pressure support, is required and when a drop in peripheral resistance and preload is clinically tolerable or beneficial. Treatment of cardiogenic shock following myocardial infarction or cardiac dysfunction following shock and reperfusion typically requires support of myocardial contractility and reduction of peripheral resistance, which makes dobutamine an excellent choice in this setting.

Epinephrine

Epinephrine, the endogenous adrenal catecholamine, is released physiologically in response to stress. It has a broad spectrum of systemic actions, including significant cardiovascular effects. When epinephrine is administered as a pharmacologic agent (0.01 to 0.05 $\mu\text{g/kg/min}$), β_1 -adrenergic effects predominate, causing increased stroke volume, heart rate, and contractility, along with modest β_2 -receptor stimulation. At higher infusion rates, α -adrenergic receptors are stimulated, which overcome β_2 -mediated peripheral vasodilation, resulting in an increase in blood pressure and SVR. Renal and splanchnic vasoconstriction, cardiac dysrhythmias, and increased myocardial oxygen demands limit the prolonged use of high-dose epinephrine. Transient increases in serum lactate have also been noted, possibly due to impaired regional blood flow. Epinephrine should be considered as a potential short-term agent for use in patients with impaired cardiac function not responsive to other agents such as dobutamine.

Norepinephrine

Norepinephrine, the sympathetic neurotransmitter, also has concentration-dependent cardiovascular effects. It should be considered as a drug with predominantly α -constrictor effects and less pronounced β -stimulation and is, therefore appropriate for use in patients who remain hypotensive despite dopamine administration or as a dopamine alternative. Combined α - and β -stimulation typically results in an increase in afterload and renal glomerular perfusion pressure, with preservation of cardiac output. Despite the potential for renal vasoconstriction, as a result of its effects on mean arterial pressure, norepinephrine is associated with an increase in urine output and creatinine clearance in hypotensive, and particularly septic, patients. A primary concern is to ensure adequate volume resuscitation prior to utilization due to risk of severe tissue damage from excessive vasoconstriction on the hypovolemic patient.

Isoproterenol

Isoproterenol is a synthetic catecholamine with potent β -adrenergic effects. From a cardiovascular standpoint, both cardiac and peripheral effects are significant. Stimulation of cardiac β_1 -receptors prompts an increase in contractility, heart rate, and conduction velocity. The chronotropic response, however, may predominate. These activities, in conjunction with peripheral vasodilation, generate significant increases in cardiac output and pulse pressure. Isoproterenol greatly increases myocardial oxygen demand and limits coronary filling due to tachycardia. As a result, indications for isoproterenol are limited to patients with hemodynamically significant bradyarrhythmias while preparations are made for electrical pacing.

Phenylephrine

Phenylephrine is a pure α -agonist and is an effective agent for increasing peripheral vascular resistance and arterial blood pressure. Although it has no direct effect on the myocardium, the increase in afterload increases left ventricular work and oxygen demand and may cause a decrease in stroke volume and cardiac output. It is often used as a first-line agent in patients with neurogenic shock, but its use is otherwise generally restricted to patients who remain hypotensive when the dosage of agents such as dopamine or norepinephrine cannot be increased due to excessive tachycardia.

Vasopressin

Vasopressin acts directly on V_1 receptors in vascular smooth muscle to cause vasoconstriction and increases the reactivity of vascular smooth muscle to catecholamines. Release of endogenous vasopressin is a normal physiologic response to shock. After septic or prolonged hemorrhagic shock, circulating vasopressin levels are decreased, possibly due to depletion of hypophyseal secretory stores. This relative deficiency may play a role in causing refractory hypotension. Vasopressin has minimal effects on normotensive patients, but in patients with septic shock, it is effective in increasing SVR and

mean arterial pressure. Vasopressin does not have inotropic properties but has potent splanchnic and coronary vasoconstrictors. It has been associated with decreased cardiac output due to myocardial ischemia and increased afterload and may worsen metabolic acidosis in patients in shock by causing splanchnic ischemia. As a result, early use of vasopressin at only physiologic concentrations to minimize associated other pressor use may be indicated in the event that other pressor agents are unable to achieve optimal perfusion.¹¹⁰

Amrinone and Milrinone

Amrinone and milrinone are noncatecholamine inotropes with cardiovascular effects similar to dobutamine, but with minimal chronotropic activity. As steroidlike phosphodiesterase antagonists, they increase smooth muscle cyclic adenosine monophosphate (cAMP) and alter calcium metabolism. Cardiac contractility, stroke volume, heart rate, and cardiac output are increased, while a concomitant reduction in afterload offsets cardiac workload. The increase in cardiac performance with minimal demands on myocardial oxygen consumption offers some utility in the treatment of cardiogenic shock or as a potential alternative to dobutamine infusion. Both agents have a relatively long half-life of nearly 3 hours and should therefore be used with caution in patients at risk of developing hypotension, a major risk in the critically ill patient.

Vasodilators

Vasodilators are used as a means to augment cardiac function through optimization of preload and afterload, both of which reduce demands on the myocardium. The failing ventricle responds to afterload reduction with significant increases in stroke volume. The reason for this is that the compromised myocardium is working past the plateau and on the down slope of the Starling curve. As a result, afterload reduction with vasodilator agents may allow cardiac output to increase, resulting in improved oxygen delivery.

Nitroprusside

Nitroprusside is a balanced but potent arterial and venous smooth muscle vasodilator. It causes a reduction in afterload that increases cardiac output and has a less prominent venodilatory effect that reduces pulmonary venous pressure and preload. Hypotension may limit its use, particularly in the presence of contractility deficits or inadequate preload. Infusions ($> 3 \mu\text{g/kg/min}$) continued for greater than 48 hours require monitoring of serum thiocyanate levels and arterial pH to detect complications of cyanide toxicity.

Nitroglycerin

Nitroglycerin is primarily a venous smooth muscle vasodilator, with less significant arterial vasodilation effects than nitroprusside. Thus, although nitroprusside predominantly decreases afterload, nitroglycerin predominantly increases venous capacitance. It is an effective treatment for acute myocardial ischemia because it reduces excessive preload and ventricular end-diastolic pressure, thereby diminishing myocardial oxygen demand.

Miscellaneous Therapeutics

Corticosteroids

In septic shock, ACTH resistance may diminish the normal cortisol response. Also, peripheral tissue resistance to corticosteroids may develop through proinflammatory-induced downregulation of normal corticosteroid receptors. Initial clinical trials showed no reduction in mortality when short courses of high-dose corticosteroids were used as adjuncts in the treatment of septic shock. However, recent studies utilizing low or physiologic doses ($< 300 \text{ mg/day}$) of hydrocortisone for a longer duration (> 5 days) of treatment have demonstrated a beneficial impact on mortality, particularly in septic patients.³⁸ Currently, routine use of ACTH stimulation tests is not advocated since they provide little more than prognostic information.⁴⁰ Given that hypoadrenal shock complicates various shock states, routine use by some experts is considered appropriate. However, this should only be based on patients who have achieved adequate intravascular volume but remain in shock despite high vasopressor administration. Thus use of corticosteroids at only physiologic doses with immediate tapering once hemodynamics have improved should be used with caution.³⁹

Metabolites and Electrolytes

Severe shock is frequently associated with hypocalcemia. Severe hypocalcemia that causes cardiac dysfunction or electrical instability should be rapidly treated. Calcium chloride rapidly corrects calcium deficits, whereas calcium gluconate must be degraded in the liver to release calcium ion, resulting in slower correction of deficits but less risk of tissue reaction. In the absence of evidence of cardiac dysfunction, attempts to restore plasma calcium to normal during shock are not warranted. Ischemia results in decreased cell membrane ATP and failure of the membrane calcium pump. Thus, reduced serum calcium levels during severe shock are probably due to movement of ionized calcium into the cells. Increased cytosolic calcium causes release of lysosomal enzymes and activation of phospholipases, protein kinases, and proteases that cause membrane damage and cytoskeletal destruction. Administration of exogenous calcium may merely worsen this uncontrolled intracellular calcium influx, whereas effective resuscitation will usually restore circulating calcium levels to normal.

Many shock resuscitation protocols emphasize correction of metabolic acidosis with fluids and inotropes until the pH begins to normalize. When interpreting an acid–base disorder, the presence of an anion gap is supportive evidence of lactic acidosis. However, a non–anion gap acidosis with worsening base deficit frequently occurs when normal saline is administered in large volumes. Efforts to correct a non–anion gap acidosis with additional fluids that may no longer be needed will only increase the risk of fluid overload.

Future Therapies

When initiating therapy for shock, the clinician does not know whether therapy has been started early, when salvage is still possible, or late, after irreversible changes have occurred within the cell and death is inevitable. Failure to respond to fluids, inotropes, and vasopressors with restoration of normal oxygen consumption and aerobic metabolism probably represents a defect in cellular and subcellular function in critical organ systems. There are many active areas of investigation that reflect the progression of our understanding of shock that have been outlined in this chapter and that have begun to move the field beyond the basics of fluid resuscitation and hemodynamic monitoring.

Efforts to control ischemia–reperfusion injury include controlled reperfusion with carbon monoxide or other compounds to reduce oxidative stress. Induced hypothermia may interrupt generation of harmful byproducts of ischemia and enable restoration of circulation and repair of structural injuries in a cellular environment where hypoxia is no longer critical. Additional biomarkers, such as procalcitonin, may allow earlier diagnosis and treatment of sepsis and shock.⁹⁹ New biosensors using near-infrared light may enable transcutaneous identification of critical limitations of blood flow and enable clinicians to more accurately target areas of regional hypoperfusion.¹¹¹ A search for agents that optimize circulation in the microvascular system by preventing activation of the endothelium may enable resuscitative efforts to restore oxygen to cells as needed to maintain normal respiration and provide critical nutrients. Ultimately, further understanding of functional genomics may enable clinicians to target transcription and translational events triggered by shock and thus alter outcome.

Chapter 10

Critical Care

Damon Clark and Heidi Frankel

Key Points

- 1 Intensive care unit (ICU) utilization is expected to increase as “baby boomers” come of age.
- 2 Surgical patients benefit from receiving critical care delivered by multidisciplinary teams led by an intensivist. Around the clock intensivist presence (24×7) may not affect mortality in ICUs with high-intensity staffing, but is thought to be most useful in those with less-intense staffing models.
- 3 Delivery of evidence-based medicine in surgical ICU patients results in improved mortality and morbidity. Streamlining comprehensively written guidelines into “bundles” and use of checklists may improve compliance and outcome.
- 4 Scoring systems have been developed and refined to address population outcome (mortality) and to quantify organ dysfunction in the ICU.
- 5 Oxygen delivery and extraction can be monitored using pulmonary artery catheters (PAC). There is no benefit to supranormalization of values in ICU patients and likely of PAC monitoring in most instances. Fluid resuscitation using functional dynamic monitoring may be more efficacious than that targeted to static values. Focused echocardiography may provide advantages to interpretation of cardiac function over more traditional methods to afford therapies that can improve outcome. Patients in cardiac arrest or impending cardiac arrest should be managed with principles outlined in current Advanced Cardiac Life Support Guidelines. One of the three rhythms that can produce pulselessness can be treated electrically, the other two require pharmacologic therapy. Dysrhythmias are treated by considering their duration and association with hemodynamic instability and heart failure.
- 6 Hypoxemia may result from mismatch of ventilation and perfusion (V/Q), anatomic or physiologic shunting, hypoventilation, or less so due to impaired diffusion. Carbon dioxide, a readily diffusible gas, is addressed by altering alveolar ventilation. Acute lung injury (ALI) and adult respiratory distress syndrome (ARDS) fall along a spectrum of pulmonary disease. Conventional ventilatory strategies incorporate a low-stretch philosophy. Evidence-based rescue strategies include prone positioning and early chemical paralysis for those with severe ARDS. Most other ventilated patients should be lightly sedated, screened for delirium, and kept moving with daily assessment for the ability to extubate. The role for airway pressure release ventilation, extracorporeal support, and inhaled prostacyclins is evolving.
- 7 Venous thromboembolism (VTE) is a significant problem in surgical ICU patients and chemical prophylaxis alone has been demonstrated to beneficially impact outcome. Low-molecular-weight heparins are more efficacious than unfractionated heparin in those at the highest risk in this population, if the risk of bleeding can be mitigated. New oral inhibitors of factors Xa and thrombin (II) have not been trialed specifically for VTE prophylaxis in general surgery ICU patients, but these agents will, undoubtedly, play a more important role in the future as more effective strategies to reverse them are developed.
- 8 A conservative transfusion trigger (7 g/dL hemoglobin) may be appropriate in most surgical ICU patients, including those with gastrointestinal bleeding, neurotrauma, cardiac disease, and sepsis.
- 9 ICU patients should undergo routine assessment and adequate support of their nutritional status to preserve lean body mass, maintain immune function, and avert metabolic complications. Enteral nutrition, delivered either gastrically or more distally, is invariably possible and preferred in most states. Earlier evidence supporting administration of immunonutrition (including components such as glutamine and omega-three fatty acids) has been refuted, although a hypocaloric, high-protein diet may be beneficial in all. Patients who are not being enterally fed, particularly those who will require mechanical ventilation for more than 48 hours or have a coagulopathy are candidates for pharmacologic prophylaxis of stress gastrointestinal bleeding. Proton pump inhibitors may be

superior to histamine-2 antagonists.

- 10 Acute kidney injury is a common complication in the surgical ICU and portends poor outcome. Few preventative measures have been proven successful short of rapid attention to diagnosis and treatment of sepsis and adequate volume resuscitation. Both continuous and intermittent dialysis may be equally effective in treating patients and may be possible even in those with hemodynamic instability.
 - 11 To balance the risks of hyperglycemia and iatrogenic hypoglycemia, glucose control in ICU patients should target levels between 140 and 180 mg/dL. Relative adrenal insufficiency is common in septic ICU patients. Hypotension unresponsive to volume loading and pressors should prompt consideration of glucocorticoid administration in this setting. Low levels of thyroid hormone may not be indicative of hypothyroidism in ICU patients and should only be treated if accompanied by clinical indications.
 - 12 Successful resuscitation of sepsis requires rapid identification of acutely ill affected patients and administration of broad-spectrum antibiotics. CVP-targeted resuscitation may be no more effective than the use of clinical endpoints. Procalcitonin assays may be beneficial to appropriately shorten the course of antibiotic therapy for bacterial infections without negatively impacting outcome. Catheter-associated infections are often preventable; their prevention requires coordinated care and various strategies, the most important of which is prompt catheter removal when no longer required. Decontamination strategies aimed at reducing ventilator associated pneumonia and methicillin-resistant *Staphylococcus aureus* infection may be efficacious.
-

Surgical patients requiring intensive care are unique in that they include those who have undergone elective procedures as well as those who have been injured or require emergent or urgent operations. As such, outcome, expectations and processes of care can be vastly different in surgical than in medical ICU patients, the majority of whom are admitted emergently. It is, thus important, to consider whether or not certain medical ICU literature is applicable to surgical patients. Most germane, mortality rates in surgical ICUs are roughly 5% to 10%, as opposed to greater than 20% in most medical ICUs.¹

1 Nonetheless, surgical ICUs and their patients share many features with those in medical ICUs. Patients admitted to the critical care unit make up a large proportion of hospital cost and resources, estimated to be roughly 1% of gross domestic product. More importantly, both surgical and medical ICUs continue to find themselves understaffed. Both the supply of critical care practitioners is inadequate and the demand is extensive, largely from aging patients with complex comorbidities undergoing complicated procedures and multitrauma. There are approximately 3,000 boarded surgical intensivists with less than 200 completing training annually, most of whom do not practice critical care exclusively. In the United States, these surgical intensivists serve largely in surgical and surgical specialty units of academic medical centers that account for approximately 10% to 15% of the nearly 6,500 ICUs with roughly 100,000 beds and 5 million admissions annually. The largest growing demographic in hospitals overall and ICUs in particular, is the group over 65 years of age, now accounting for over half of all admissions, resulting in ICUs practicing at over two-thirds of capacity.

ORGANIZATIONAL STRUCTURE OF CRITICAL CARE

The intensive care unit provides an environment that allows close monitoring and care by experienced physicians, nurses, and other ancillary staff. Current ICUs have the following common features: (1) a designated geographical space, (2) specialized monitoring and therapeutic capabilities, (3) resources to provide continuous care, (4) appropriate nurse to patient ratio, and (5) specialized personnel. There is controversy, particularly in surgical ICUs, as to how superspecialized they need be (visceral transplant vs. cardiac surgery vs. noncardiac thoracic surgery). Practically, this is an issue of institutional volume and expertise as there is little data to support superspecialization in surgical units (neurosurgical patients, a notable exception). Diagnostic and therapeutic capabilities include invasive and minimally invasive cardiac monitoring, basic and rescue modes of ventilation and adjuncts, extracorporeal support, dialysis and hepatic support, and neurologic monitoring, as described below. ICU nurse to patient ratios vary from 1:3 to 2:1 depending on patient acuity and therapeutic needs that may be addressed with a scoring system such as the therapeutic intervention severity score (TISS).³ Finally, dedicated pharmacists, dietitians, physical therapists, and advanced level practitioners such as acute care nurse

practitioners have all been demonstrated to improve process compliance and patient outcomes.⁴⁻⁷

Traditionally there are two types of ICU organizational structures: open and closed formats. In an open ICU, the patients are admitted under the supervision and care of the primary physician/surgeon. The primary physician or surgeon is responsible for providing patient care including order entry and communication with the family, with ultimate decision making power over clinical decisions. The primary physician/surgeon also continues to care for patients in other areas of the hospital, providing both continuity, but also deflecting focus from the moment to moment care of the most acutely ill and injured in the ICU. In the open format, the primary physician has the opportunity for consultation of an intensivist. Within a closed format ICU, the patient's care is transferred to an intensivist whose only responsibility is to take care of patients within the ICU. Of course, hybrid models exist regarding division of labor with respect to order entry and family communication. A multidisciplinary team led by an intensivist can function in either closed or open structures (utilizing the intensivist in the consultant role in the open format); however, the ability to provide immediate and continuous care may be compromised in fully open surgical ICUs. In fact, the benefit of a high-intensity staffing model (with an intensivist-led team or mandatory intensivist consultation) is more apparent in surgical than in medical ICUs (perhaps due to the difficulty of an operative surgeon to simultaneously manage an ICU patient), with a 15% decrease in ICU mortality.^{8,9} There is other work that specifically points to the benefit of a closed ICU structure in decreasing morbidity and mortality.^{10,11,12} Nonetheless, despite the care model employed, exquisite communication between members of the primary surgical team, ICU team, patient (if possible), and family is mandatory to ensure best outcome and satisfaction by all. In recognition of this, in the United States, The Joint Commission for Accreditation of Hospital Organizations (TJC) requires a handoff between members of the surgical and ICU teams when a patient is admitted to the ICU from the operating suites.¹³

2 The natural progression of work on the success of a high-intensity ICU staffing model on outcome would be to promote around the clock availability of such services.¹⁴ However, these 24/7 intensivist models did not improve SICU mortality in several studies and reviews, although they reduced morbidity and resource utilization in others.¹⁵⁻¹⁷ This may be a consequence of the fact that studies examining the effect of around the clock care have largely been carried out at academic medical centers with robust nighttime fellow coverage.¹⁸ A noctensivist can improve morbidity and mortality in ICUs with low-intensity staffing.

Finally, a taskforce rendered recommendations on the appropriate intensivist/patient ratio in teaching institutions. A ratio of one intensivist to 14 patients should be maintained to ensure timely completion of rounds, staff satisfaction, and provision of high quality patient care and education of trainees.¹⁹

Evidence-Based Care

Numerous extensively researched evidence-based guidelines have been developed covering many aspects of critical care, including the management of sepsis, ventilator management, and administration of nutrition among others, the most important of which will be discussed below.²⁰

3 The most robust evidence lends itself to the multidisciplinary, multiprofessional development of institutional protocols and clinical practice guidelines. Unfortunately, without electronic prompts or other mechanisms in place, compliance by even well-intentioned practitioners may be less than ideal. Thus, ICU care providers have developed memory aids in the form of checklists and bundles. Further, this simplification of ICU processes, which, in turn, may improve outcome, lends itself to regulatory scrutiny.

Checklists do not necessarily reinforce evidence-based care (although they certainly can). They are meant to embody crew resource management strategies. The use of a daily goals checklist in the ICU enables practitioners to ensure that important components of care are addressed. Vincent described the acronym "FAST HUG" as a simple checklist mnemonic for ICU use (Table 10-1).²¹

In our ICU, we have added a component to each of the letters. Use of these checklists improves the knowledge of the game plan by the entire care team. Pronovost and colleagues demonstrated that use of a daily goals sheet improved understanding of the daily plan from 10% to 95% and effected a decreased ICU length of stay.²²

Table 10-1A FAST HUG

F	Feeding	Can the patient tolerate oral and/or enteral feeds?
A	Analgesia	Patient should not be in pain nor receive excessive analgesia
S	Sedation	Patient should not experience discomfort but should be arousable
T	Thromboembolic prevention	With chemical or mechanical adjuncts
H	HOB elevated	Optimal 30–45 degrees
U	Stress ulcers	H2 antagonists or PPI
G	Glucose control	Blood sugar levels and treatment

H2: histamine 2, PPI: proton pump inhibitor, HOB: head of bed.
From Vincent JL. Give your patient a fast hug (at least) once a day. *Crit Care Med* 2005;33(6):1225–1230, with permission.

Bundles

The process of bundling evidence-based care practices allows ICUs to keep up with regulatory changes and practice the most up to date critical care practices. Unlike checklists, ICU care bundles are always evidence based. Bundles are comprised of interrelated processes and have a limited number of elements (typically three to seven) whose key processes must be carried out in the same space and time. Bundles exist addressing ventilator-associated pneumonia, central line infection, catheter-associated urinary tract infection and pressure ulcer prevention, diagnosis and treatment of sepsis, and promotion of palliative care. Large collaborative groups in the United States, including the Voluntary Hospital Association, The Institute for Healthcare Improvement and the Michigan Health and Hospital Association-Keystone Project, have shown improved patient outcomes after implementation of various bundles.²³ Continuing education is required to maintain appropriate use and compliance with these management bundles. The implementation and use of sepsis resuscitation bundle and management bundle were significantly improved after 2 month nationwide education effort to improve compliance with the care for patients with severe sepsis.²⁴ These evidence-based guidelines and bundles have been shown to improve mortality and decrease morbidity and ICU related complications. Severe sepsis and septic shock bundles are associated with reduced in-hospital mortality (Table 10-2). Mortality rates in these centers using severe sepsis and septic shock bundles decreased by 16.7%.²⁵ It has also been shown that the implementation of central venous catheter care bundles led to decreased central line associated blood stream infections (Table 10-3).²⁶ Awakening, breathing, coordination, delirium, and early mobility (ABCDE) bundles show some improvement in ICU average length of stay and average days on mechanical ventilation.²⁷ Finally, some have “bundled” a variety of these disparate bundles together to drive global evidence-based care. The Surgical Care Improvement Project (SCIP) guidelines are perhaps the most relevant and robust example.

Table 10-1B Extended FAST HUG – as Modified by the Authors from above

F	Family and fluids	Family updated. Volume status assessment and fluid balance goals.
A	Analgesia and antibiotics	Pain control goals. Cultures and appropriate antibiotics.
S	Sedation and swallow	Sedation goals. Nutrition goals and metrics
T	Thromboprophylaxis and tube/lines	DVT prophylaxis. Need for central lines, urinary catheters, and other devices.
H	HOB/PT/OT	Ambulation, OOB, and physical and occupational therapy
U	Ulcers	Peptic and pressure ulcer prevention and skin assessment and care
G	Glucose and gas exchange	Blood sugar levels and treatment. Ventilator and pulmonary needs.

HOB: head of bed, PT: physical therapy, OT: occupational therapy, OOB: out of bed

Table 10-2 Surviving Sepsis Care Bundle

Complete Within 3 hrs	Complete Within 6 hrs
Measure lactate level	Administer vasopressors for persistent hypotension or lactate elevation after volume resuscitation
Obtain blood cultures prior to antibiotics	Measure CVP and ScvO ₂ for persistent hypotension after volume resuscitation
Administer broad spectrum antibiotics	Repeat lactate if initial was high
Administer 30 mL/kg crystalloid for hypotension and lactate >4 mmol/L	

CVP: central venous pressure, ScvO₂: central venous oxygen saturation.
From Dellinger RP, Levy MM, Rhodes A, et al. Surviving sepsis campaign: international guidelines for management of severe sepsis and septic shock: 2012. *Crit Care Med* 2013;41:580, with permission.

The application of evidence-based guidelines into clinical practice, even facilitated by use of bundles, is often difficult. Educational and quality improvement programs, described above, can improve the implementation of and compliance with these evidence-based guidelines. Further, it is important to realize that bundles and any evidence-based guidelines must be continuously updated as new information comes to the fore, particularly if the level of evidence or strength of recommendation was weak. Examples in the care of the septic patient will be discussed below. Finally, although use of bundles can promote team-building by providing objective feedback of performance, competent and individualized clinical decision-making should not be sacrificed.

Table 10-3 Central Line Associated Bloodstream Infection (CLABSI) Bundle

Hand hygiene – antisepsis before and after procedure
Chlorhexidine – antiseptic skin preparation before catheter insertion
Sterile precautions – hat, mask with sterile gown, gloves, and full length drapes
Catheter site – subclavian vein preferred
Daily review of line need and removal of unnecessary lines.

Table 10-4 Comparison of ICU Scoring Systems

Scoring System	Required Variables	Time of Data Collection	Estimated Parameters
APACHE IV	Physiologic data, ICU admission diagnosis, co-morbidities, age, LOS before ICU admission, emergency surgery, thrombolytic therapy, mechanical ventilation	First ICU day	APACHE IV score, predicted hospital mortality and ICU LOS
MPMO-III	Physiologic data, ICU admission diagnosis, comorbidities, age, LOS before ICU admission, vasopressors, type of admission, infections	At ICU admission	Predicted hospital mortality and ICU LOS
SAPS 3	Physiologic data, acute diagnosis and anatomical site of surgeries, comorbidities, age, LOS before ICU admission, vasopressors, type of admission, infections	At ICU admission	SAPS 3 score and predicted hospital mortality. Customized equations for seven different geographic regions

ICU: Intensive care unit, LOS: length of stay, APACHE: Acute Physiology and Chronic Health Evaluation, SAPS: Simplified Acute Physiology Score.
From Salluh JIF, Soares M. ICU severity of illness scores: APACHE, SAPS and MPM. *Curr Opin Crit Care* 2014;20:557–565, with permission.

CRITICAL CARE PROGNOSTICATION AND SCORING

4 ICU scoring systems have been used to provide a framework to describe patients' severity of illness for the routine evaluation of ICU performance, quality improvement initiatives and to prognosticate outcome.²⁸ The most robust prognostication systems compare observed and risk-adjusted hospital mortality for critically ill patient groups derived from analysis of large data sets. They operate on the premise that early physiologic derangements prior to resuscitation and therapy present early in the ICU admission will influence hospital mortality. Other systems have been developed to quantify organ dysfunction and therapeutic interventions predicted.

The ideal scoring system should be valid, reliable, calibrated, discriminating, and simple. The Glasgow coma scale score is an apt example. However, since ICU patients are heterogeneous, documentation is often incomplete and practices are not standardized, such a system is not available in

the ICU. The most frequently used severity of illness scores in an adult ICU used to prognosticate hospital mortality are Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Model (MPM), and the Simplified Acute Physiology Score (SAPS) with higher scores portending increased hospital mortality. APACHE and MPM were developed using data predominantly from the United States; SAPS was more global (Table 10-4). To stay relevant and useful, these scoring systems require and have undergone regular updates and regional customizations. These scoring systems are currently in their third and fourth generations. It is vital to remember that these scoring systems provide prognostication for the outcome of an ICU population more accurately than for an isolated patient.

APACHE was developed several decades ago by William Knaus and colleagues at George Washington University. The inaugural version ranked 34 acute variables from one to four and weighted chronic health conditions A to D to render a score with higher numbers suggesting more acutely ill patients. Versions two and three decreased the acute variable to 12 and 17, respectively, and created a simpler way to weight the chronic health evaluation. The proprietary (and expensive) version, APACHE III, never had large market penetration and was much more complex than earlier versions. APACHE IV²⁹ which included more variables has many components in the public domain; however, without a regulatory requirement to provide risk-adjusted ICU metrics and the need to employ personnel to verify and interpret data, it is also not widely used. Further, since the data is collected at the time of ICU admission, the possibility of lead-time bias exists. APACHE provides an algorithm for prediction of ICU length of stay. Several studies have indicated that the current version of APACHE, although labor intensive, is more accurate in prognosticating outcome due to better calibration and discrimination with fewer excluded patients. This is particularly true for surgical patients.

SAPS shared many variables and weightings common with APACHE but provided separate prognostication for medical, scheduled and unscheduled surgical patients; cardiac and burn patients are excluded.³⁰ Further, it provides customizable equations to predict outcome according to seven distinct geographic locations.

The MPM uses dichotomous physiologic (not laboratory) variables for the most part (simplifying data collection), collecting data both upon admission and at 24 hours to measure mortality risk at 24 and 48 hours. However, it excludes more patients than does APACHE. MPM-III has been further modified with additional variables and different patient exclusions and is known as the ICU Outcomes Model (ICOM) that has been endorsed by the National Quality Forum of the United States for public reporting of risk-adjusted hospital mortality of ICU patients.³¹

The future of ICU prognostication may well involve interpretation of “big data” that relies less on traditional data acquisition and storage and more on linear or logistic regression modeling. Much work must be done in this realm before practical applications are available.³²

Several organ failure scores exist as well, designed to link homogeneous patients for the purpose of clinical trials and quality assessment. They can be used to provide initial as well as serial assessments. The SOFA and Marshall scores consider variables in six categories (respiratory, cardiovascular, hematologic, central nervous system, renal, and hepatic). The Denver score excludes the hematologic and neurologic components. A Marshall or Denver score greater than or equal to 4 implies multiorgan dysfunction (Table 10-5).^{33,34}

TISS provides a sum of all interventions in physiologic categories to assist with resource utilization.

HEMODYNAMIC MONITORING AND TREATMENT

Oxygen Delivery and Consumption

Oxygen delivery (DO_2), the rate at which oxygen is transported to the microcirculation from the lungs, is the product of cardiac output and arterial oxygen content (CaO_2) and is normally about 1,000 mL/min. CaO_2 , in turn, is the product of hemoglobin and oxygen saturation (SaO_2) multiplied by 1.34 (g oxygen per 100 mL hemoglobin) added to the partial pressure of oxygen (PaO_2) multiplied by 0.003. Thus, delivery falls in instances of cardiac failure, hypovolemia, anemia, or less so due to poor oxygenation. Oxygen consumption (VO_2), the rate at which oxygen is removed from the blood by the microcirculation, is the product of cardiac output and the arteriovenous O_2 difference ($\text{CaO}_2 - \text{CvO}_2$) and is normally 250 mL/min in an average adult. Thus, oxygen extraction (OE) ratio or the ratio of VO_2 to DO_2 is normally about 25%. (The myocardium has the body's highest extraction ratio at

approximately 75%.) Consumption remains constant over a wide range of DO_2 by changes in OE. For example, in situations of decreased delivery such as hemorrhagic or cardiogenic shock, consumption can be maintained by increasing the extraction ratio. This mechanism may be altered in critically ill patients who show marked increases in consumption under the influence of stress hormones and catecholamines. However, there is little evidence that artificially augmenting DO_2 to so-called supranormal levels by means of inotropes or red cell transfusion results in improvement in morbidity or mortality.

Table 10-5 Marshall Multiple Organ Dysfunction Syndrome (MODS) Versus Denver Multiple Organ Failure (MOF) Organ Failure Scores

Marshall MODS	Grade 0	Grade 1	Grade 2	Grade 3	Grade 4
Pulmonary $\text{PaO}_2/\text{FiO}_2$ ratio	>300	226–300	151–225	76–150	<75
Renal Cr, $\mu\text{mol/L}$	<100	101–200	201–350	351–500	>500
Hepatic total bili, $\mu\text{mol/L}$	<20	21–60	61–120	121–240	>240
Cardiovascular (PAR)	<10	10.1–15	15.1–20	20.1–30	>30
GCS	15	13–14	10–12	7–9	<6
Platelet count $\times 10^3$	>120	81–120	51–80	21–50	<20
Denver MOF	Grade 0	Grade 1	Grade 2	Grade 3	
Pulmonary $\text{PaO}_2/\text{FiO}_2$ ratio	>250	250–200	200–100	<100	
Renal Cr, $\mu\text{mol/L}$	<159	160–210	211–420	>420	
Hepatic total bili $\mu\text{mol/L}$	<34	34–68	68–137	>137	
Cardiac Inotropes	None	One low dose	>1 agent at low dose or 1 at moderate dose	>2 agents at moderated dose or any at large dose	

PaO_2 : partial pressure of oxygen in arterial blood, FiO_2 : fraction of inspired oxygen, Cr: creatinine.
 From Marshall JC, Baue AE, Berlot G, et al. Multiple Organ Dysfunction (MOD) score. In: *Sepsis and Organ Dysfunction*. Springer-Verlag; 1998;45–51 and Moore FA, Sauaia A, Moore EE, et al. Postinjury multiple organ failure: a bimodal phenomenon. *J Trauma* 1996;40:501–502.

Mixed venous oxygen saturation (SvO_2) is expressed as $1 - \text{VO}_2/\text{DO}_2$, with normal values of 60% to 80% that can be continuously displayed with an oximetric pulmonary artery catheter or measured from the distal port. Reductions in SvO_2 reflect a mismatch between DO_2 and VO_2 (Table 10-6).

Hemodynamic Monitoring

Assessment of volume status and cardiac function of the critically ill patient is evolving. Traditional static measures of volume assessment using central and pulmonary artery catheters (PACs) are being replaced in many settings by dynamic or functional measures afforded by technologies such as pulse waveform analysis and focused cardiac ultrasound (ECHO). Similarly, indirect measurement of cardiac function by PACs is being subsumed by pulse waveform analysis and systolic and diastolic evaluation of left and right global and regional function using ECHO.

Assessment of Fluid Responsiveness

The concept of volume status using static measures has evolved to “volume responsiveness” using dynamic or functional measures to assess whether a fluid bolus will improve the stroke volume (SV) and cardiac performance of a critically ill patient, the principal goal of resuscitation. Static measures such as central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) can give inferential data of cardiac filling pressures at a single time-point, which then extrapolates to cardiac preload (end diastolic volume) and volume status of the patient. However, these pressures can be altered depending on cardiopulmonary physiology, do not always correlate with Frank–Starling principles, and give no indication of whether the patient will respond to a bolus of infused fluid, which is ultimately what those tasked with resuscitation want to know.

Static measures of volume status include assay of CVP and PAOP. These measures are made at end expiration when the pleural pressure is closest to atmospheric pressure. Normal venous waveform components include the “a” wave (corresponding to atrial contraction), the “c” wave (tricuspid valve closure and isovolumic right ventricular contraction), and the “v” wave (ventricular ejection driving venous filling of the atrium) (Fig. 10-1). Clinically, the high point of the “a” wave is the atrial pressure at maximum contraction, where atrial pressure is greater than ventricular diastolic pressure. Here, the atrium is contracted and the tricuspid valve is open, which is synonymous with right ventricular end diastolic pressure, making the ventricle, atrium, and vena cava interconnected. Optimally, this is the point at which the CVP is measured. Unfortunately, many intracardiac and extracardiac interactions can

alter these pressure relationships in the vena cava and diseased heart, and, thus, affect the CVP waveform. For example, atrial fibrillation fails to produce an “a” wave, and AV-dissociation produces irregular augmented (cannon) “a” waves with absent “c” and “v” waves, making calculation of mean CVP difficult. Tricuspid regurgitation and tamponade may produce augmentation of the v wave and falsely imply adequate or increased intravascular volume in a patient who may be hypovolemic. Thus, the CVP waveform may fail to provide an adequate reflection of volume responsiveness in diseased states.

Table 10-6 Oxygen Delivery and Consumption Equations

$DO_2 = CO \times CaO_2$
Oxygen delivery in mL/min
$CaO_2 = SaO_2 \times 1.36 \times Hgb + 0.003 \times PaO_2$
Arterial oxygen content
$VO_2 = CO \times (CaO_2 - CvO_2)$
Oxygen consumption in mL/min
$OE = VO_2/DO_2$
Oxygen extraction ratio
$SvO_2 = 1 - VO_2/DO_2$
Mixed venous oxygen saturation

DO₂: oxygen delivery, CO: cardiac output, CaO₂: arterial oxygen content, SaO₂: oxygen saturation, PaO₂: partial pressure of oxygen in arterial blood, VO₂: oxygen consumption, CvO₂: central venous oxygen content, OE: oxygen extraction, SvO₂: mixed venous oxygen saturation.

Figure 10-1. Normal venous waveform with ECG.

5 Further, the use of CVP to guide resuscitation has not been demonstrated to be beneficial in many large clinical series. A large meta-analysis revealed a very poor relationship between CVP and blood volume.³⁵ Additionally, several large recent trials of sepsis resuscitation demonstrated that resuscitation targeted to CVP endpoints did not improve outcome.^{36,37}

Pulmonary artery catheter-based volume assessment employs the principle that a single column of fluid forms from the pulmonary artery to the left ventricle during diastole. For a given left ventricular end-diastolic pressure (LVEDP) and compliance, left ventricular end-diastolic volume (LVEDV) can be estimated. Based on the Frank–Starling principle, the force of ventricular contraction is proportional to muscle stretch and LVEDV, thus as PAOP estimates LVEDV for a given cardiac output, preload may be determined. Numerous physiologic changes may alter the relationship between PAOP and LVEDV, including veno-occlusive disease, pulmonary hypertension, ARDS, increased intrathoracic pressure, valvular disease, and altered cardiac compliance. Finally, large clinical trials have failed to demonstrate a benefit to outcome for those resuscitated to a PAOP endpoint.³⁸

Dynamic or functional measures of volume responsiveness include those on both the arterial side and venous side of the heart. Normally, the inspiratory increase in pleural pressure during positive pressure breathing reduces right ventricular preload and stroke volume, manifested on the arterial side within two to three beats in most. Left ventricular stroke volume diminution is maximal during expiration. These normal physiologic changes during the mechanically supported respiratory cycle are augmented with hypovolemia that is volume responsive. Pulse waveform analysis uses analysis of the arterial

pressure waveform. The area under the curve corresponding to systole (i.e., before the dicrotic notch) is used to calculate stroke volume (Fig. 10-2). Computer calculation is made of the maximal and minimal amplitude of the curve. In general, a variation in stroke volume (SVV) of greater than 13% to 15% reflects volume responsiveness, whereas values below this threshold imply that the patient is beyond the upper inflection point of the Frank–Starling curve, and will not benefit from further volume loading. There are instances where it is possible to misinterpret these values. For example, high vasopressor burden or lack of arterial compliance (such as in diffuse atherosclerosis) may alter blood flow and arterial wave morphology, respectively. However, clinical applications of SVV as a volume assessment tool have been promising.³⁹

Venous assessment of volume responsiveness is performed by ECHO, which can also perform arterial side estimation. ECHO can provide volume assessment with both static and dynamic values. Further, many static measures can be rendered functional by performing measurements both before and after a passive leg raise, a maneuver that replicates volume loading. Passive leg raising measurements may be the only accurate methodology to approximate fluid responsiveness in spontaneously breathing patients. In these patients, a breath results in an increase in SV and systolic pressure. Static values include measurement of the inferior vena cava (IVC) on the long axis view, or in some series by the superior vena cava (SVC) or internal jugular vein (IJV) on the venous side or calculation of the velocity time integral (VTI) on the arterial side. Collapsibility of the IVC (or SVC/IJV) of at least 15% and as much as 50% during respiration predicts fluid responsiveness.⁴⁰ Right-sided heart failure may alter the size relationships of the central veins, thus providing an underestimate of fluid responsiveness using venous measurements (lack of respiratory variation due to pressure overload and diminished venous return to the heart). Arterial assessments are typically done of aortic blood velocity approximated from the VTI.

Assessment of Cardiac Function is best understood by recollection of the cardiac pressure–volume curve depicting the cardiac cycle (Fig. 10-3). Starting at the top right at “A,” the aortic valve opens and blood is ejected into the outflow tract. At “B” systole ends as the aortic valve closes. A period of isovolumic relaxation occurs and ventricular pressure falls until the mitral valve opens at “C,” the start of diastole. Diastole ends as the mitral valve closes at “D” and then there is a period of isovolumic contraction with both valves closed until the cycle repeats. Note that the distance across the box represents SV. SV is the amount of blood ejected per beat and is expressed in mL and determined by preload, afterload, and contractility. The product of SV and heart rate is CO. Ejection fraction (EF), a more valid estimate of cardiac function, is the proportion of preload or EDV ejected per beat or SV/EDV.

Figure 10-2. Arterial pressure waveform. Area under systole curve is used to calculate stroke volume. pSBP, peripheral systolic blood pressure; pPP, peripheral pulse pressure; pDBP, peripheral diastolic blood pressure.

Figure 10-3. Left ventricular pressure–volume curve. Ees, LV elastance; Ea, arterial elastance; ESV, end-systolic volume; EDV, end-diastolic volume; ESP, end-systolic pressure; EDP, end-diastolic pressure; LV, left ventricle. **A:** aortic valve opens; **B:** aortic valve closes; **C:** mitral valve opens; **D:** mitral valve closes.

PA catheters determine cardiac output by thermodilution. The thermodilution technique measures temperature changes sensed by a balloon at the distal end of the catheter after a cold saline injection is performed through the proximal port. Based on the modified Stewart–Hamilton equation, which constructs a plot of temperature change against time, measurements of cardiac output can be obtained. Thermodilution technique assumes that complete mixing of the blood occurs, that there is constant blood flow in the heart, and that there is no loss in concentration of the indicator between the point of injection and the distal balloon tip. Slow injections, incorrect volumes of injectate, incorrect temperature of injectate, either isolated or in combination with anatomic and physiologic cardiac derangements can alter the accuracy of cardiac output determination.

Pulse contour analysis can also be used to measure stroke volume (and hence cardiac output). Using PAC thermodilution as the gold standard, accuracy is acceptable.

ECHO does not suffer from many of the shortcomings of CVP, PAC, or arterial line assessment with regard to the assessment of cardiac function. ECHO can determine left ventricular function (systolic and diastolic), right ventricular function, and assess wall motion abnormalities, valve defects, pericardial fluid, and provide real-time information on effectiveness of inotropic and vasopressor therapy. ECHO can provide information about heart function in a qualitative or quantitative fashion – it can be used to assess left and right heart morphology, dynamics, and size, and can determine the difference in EF and stroke volume, and perform quantitative estimates of pulmonary artery and right ventricular pressure. ECHO is unique in that it is the only tool available that can provide EF data in addition to SV (CO). Shock states may be due to impaired EF or contractility (requiring inotropy) or due to diminished volume status and stroke volume (requiring fluid), which is not discernable with a PAC. Various ECHO methodologies are available to determine and measure EF, including a purely qualitative one that is reasonably accurate compared to quantitative means.

ECHO can also discern right heart dysfunction, very common in surgical ICU patients by examining size, morphology and function of the right ventricle. Underfilling of the left heart, typically treated by volume loading, requires attention to inotropic support in the case of right heart failure. Finally, unique to ECHO is the ability to assess for diastolic dysfunction as occurs with sepsis, tamponade, and increased pleural pressure (as with pneumothorax, abdominal compartment syndrome, and massive pleural effusions).

TREATMENT OF CARDIAC ARREST AND DYSRHYTHMIAS

Dysrhythmias are extraordinarily common in both cardiac and noncardiac surgical ICU patients. Those most life-threatening can be treated by following current American Heart Association Advanced Cardiac Life Support (ACLS) guidelines.⁴¹ For patients who become pulseless in the ICU, rapid restoration of the circulation employing basic life support strategies (BLS) is vital. The most important features of the current BLS guidelines include the recognition that cardiopulmonary resuscitation (CPR), when indicated, be delivered by pushing hard and fast with complete recoil at a rate of at least 100 compressions/min to a depth of 2 in in adults. CPR providers should deliver no more than 2 minutes of

therapy each (or five cycles of compressions) until a personnel switch is made. In adults, the ratio of 30 compressions to 2 breaths is maintained until ventilation can be controlled by intubation and controlled ventilation. Cricoid pressure is not recommended in current ACLS guidelines. Further, the rapid use of a defibrillator is key to improving postarrest survival. Of course, in ICU patients, cardiac arrest is often witnessed and the underlying rhythm known and may not respond to defibrillation. Sadly, cardiac arrest from a rhythm other than ventricular fibrillation, such as from bradycardia progressing to asystole or pulseless electrical activity (PEA), portends a poor prognosis, often as the result of acidosis or profound hypoxia incidental to sepsis and multiple organ failure. Another important feature of the current BLS and ACLS guidelines that may impact surgical ICU patients is the recognition of the need for postcardiac arrest care. This certainly includes fluid resuscitation and administration of pressors and inotropes as needed. However, there may also be a need to interrogate via coronary angiography and treat for acute coronary syndrome if anticoagulation can be tolerated and for consideration of postarrest hypothermia to preserve neurologic function. Although hypothermia protocols were established to address out of hospital cardiac arrest with coma, there has been increasing use of the modality for hospitalized patients as well. Current guidelines also address new technology with biphasic electrical sources that deliver shocks for dysrhythmias with a pulse and defibrillation in those with ventricular fibrillation. Another important component of the recommendations is the use of end-tidal CO₂ monitoring to ensure adequacy of CPR quality.

Three dysrhythmias produce pulselessness: ventricular fibrillation, asystole, and PEA. Only ventricular fibrillation is responsive to defibrillation which is with 120 to 200 J using a biphasic device as per manufacturer's recommendations. PEA and asystole are treated by administration of epinephrine (1 mg every 3 to 5 minutes) and/or vasopressin (40 U one-time dose). Pulseless ventricular tachycardia is treated like ventricular fibrillation with additional shocks given after five cycles of CPR (2 minutes). In addition, epinephrine and vasopressin are administered as CPR continues. Continued pulseless ventricular tachycardia and fibrillation can be treated with amiodarone (300 mg with a second dose of 150 mg if refractory) or lidocaine (1.0 to 1.5 mg/kg).

For the remainder of dysrhythmias, several key features should be noted. Is the patient, hemodynamically stable or unstable? Is the EF normal or altered? Is the dysrhythmia acute or long standing? Hemodynamic instability in association with a rhythm disturbance often renders electrical therapy more desirable, if possible. In those with a low EF, antiarrhythmics that are also negative inotropes should be avoided. Finally, even duration of as little as 48 hours can increase the risk of thrombotic complications of some dysrhythmias (e.g., atrial fibrillation) and can alter therapeutic decisions.

PULMONARY GAS EXCHANGE

Consists of the intake of oxygen by pulmonary capillaries from the alveoli and the excretion of carbon dioxide in expired breaths.

Oxygenation

Normal lung function and gas exchange require patent and dry alveoli with a narrow interface with the pulmonary capillaries. Once red blood cells become saturated with oxygen, the rest dissolves into the plasma and the measured partial pressure of oxygen (PO₂) is 100 mm Hg with an oxygen saturation (SaO₂) of 100%. Since a small portion of blood is diverted away from the pulmonary circulation (via bronchial vessels), a normal PaO₂ is 90 mm Hg with 98% saturation. Insufficient blood oxygenation is termed hypoxemia. This is to be differentiated from hypoxia, which is abnormally low oxygen content in a tissue or organ. The alveolar to arterial (A-a) oxygen gradient is a common measure of oxygenation ("A" denotes alveolar and "a" denotes arterial oxygenation). PaO₂ is measured by arterial blood gas, while PAO₂ is calculated using the alveolar gas equation: $PAO_2 = (FiO_2 \times [P_{atm} - P_{H_2O}]) - (PaCO_2 \div R)$ where FiO₂ is the fraction of inspired oxygen (0.21 at room air), P_{atm} is the atmospheric pressure (760 mm Hg at sea level), P_{H₂O} is the partial pressure of water (47 mm Hg at 37°C), PaCO₂ is the arterial carbon dioxide tension, and R is the respiratory quotient. The normal gradient is about 10 mm Hg. Dividing the PaO₂ by the FiO₂ estimates the A-a gradient, which normally approximates 500.

Perturbations causing hypoxia and hypoxemia may be the result of hypoventilation relative to perfusion (V/Q mismatch), impaired diffusion, or shunt. Hypoventilation, a result of neuromuscular dysfunction (or more typically iatrogenic due to medications) and impaired diffusion (occurring with

pulmonary edema or interstitial lung disease) can be treated effectively by exogenous administration of oxygen. The A-a gradient is normal in hypoxemia due to pure hypoventilation and increased in V/Q mismatch. V/Q mismatch, the cause of most hypoxemia in the ICU, occurs with decreased airflow to the alveoli in relation to the amount of pulmonary capillary blood flow. In the normal lung, there is V/Q mismatch because perfusion and ventilation are heterogeneous. Both ventilation and perfusion are greater in the bases than in the apices. However, the difference between apical and basilar ventilation is less than the difference between apical and basilar perfusion. Therefore, the V/Q ratio is higher in the apices than in the bases. In the diseased lung, V/Q mismatch increases because heterogeneity of both ventilation and perfusion worsen resulting in hypoxemia. Common causes of hypoxemia due to V/Q mismatch include obstructive lung diseases, pulmonary vascular diseases, and interstitial diseases. Shunting occurs when there is adequate ventilation of the alveoli but decreased pulmonary capillary blood flow. Shunting may be anatomic as with intracardiac shunts and hepatopulmonary syndrome or physiologic as when nonventilated alveoli are perfused as with pneumonia. Hypoxia due to shunting with venous admixture as with severely depressed cardiac output or anemia cannot be overcome by administration of oxygen (Fig. 10-4).

Figure 10-4. West lung zones. Zone 1: Not observed in healthy lung. Alveolar pressure exceeds pulmonary blood vessel pressure leading to alveolar dead space. Zone 2: Located approximately 3 cm above heart. Pulmonary vessel pressure exceeds alveolar pressure in a pulsatile fashion and allows pulmonary blood flow and alveolar distention. Zone 3: Majority of healthy lungs with continuous blood flow and oxygenation. P_A , Alveolar Pressure; P_a , arterial pressure; P_v , venous pressure.

Ventilation and CO₂ Removal

Ventilation refers to the exchange of air from the atmosphere to the lungs and alveoli. The rate at which alveolar ventilation occurs determines the amount of carbon dioxide (CO₂) excretion, a readily diffusible substance. The amount of CO₂ produced and requiring elimination is related to the respiratory quotient (RQ). RQ is the ratio of CO₂ produced to O₂ consumed and is normally 0.8, depending on the diet. Chemoreceptors in the medulla are responsive to pH changes and when patients become acidotic they hyperventilate to decrease PaCO₂ to maintain homeostasis at 40 mm Hg. End tidal CO₂ may be lower than PaCO₂ if substantial lung is ventilated but not perfused (dead space).

Pulmonary Mechanics

The relationship between ventilatory volumes and pressures is referred to as pulmonary mechanics and depends on compliance. The functional lung in acute lung injury is smaller with heterogeneous disease, necessitating a protective lung strategy of ventilation that will be described below.

Figure 10-5. Flow-time scalar showing autoPEEP.

VENTILATOR MODES AND GRAPHICS

One of the initial steps in evaluating a patient with respiratory failure is to establish a patent and

protected airway. The ICU team must determine if the patient has an acute issue causing the respiratory failure that can be treated without mechanical ventilation. Through the use of physical examination, bedside ultrasound and radiography, the ICU team may diagnose a pneumothorax or acute pulmonary edema that can be treated without intubation. If the patient has acute respiratory failure without an easily treatable process, intubation and mechanical ventilation may be safest. When setting up the mechanical ventilator there are several options and modalities from which to select.

Mechanical ventilation improves oxygenation and ventilation by attempting to improve V/Q mismatch by decreasing the amount of shunt. Current recommendations are for low tidal volume (V_t) settings of 6 to 8 mL/kg for the prevention of barotrauma in surgical ICU patients.⁴² Respiratory Rate (RR) is typically set at 12 to 16 breaths/min. RR is altered to achieve an optimal PaCO_2 . Positive end expiratory pressure (PEEP) is applied to prevent significant alveolar collapse during expiration and is particularly important in low lung volume ventilation strategies. PEEP is typically started at 5 cm H_2O but can be titrated up to improve oxygenation. The initial setting for patients with respiratory failure is an FiO_2 of 1.0. After initial check of ABG the FiO_2 is weaned down to maintain a minimal PaO_2 of 60 mm Hg and O_2 saturation of $>90\%$ with goals of $\text{FiO}_2 < 0.4$ to prevent O_2 toxicity.

Ventilatory mechanics can be displayed graphically and include scalars and loops. Scalars are plots against time – either flow, pressure, or volume. Several loops are helpful clinically and include the pressure–volume and flow–volume loops. Each graphic can be important in demonstrating a physiologic anomaly and displays a certain pattern depending on the ventilator mode. The flow versus time scalar is helpful for identifying air trapping or auto-PEEP that can accompany certain ventilator modes (Fig. 10-5). This can result in barotrauma or hemodynamic instability. Measures to decrease auto-PEEP include decreasing tidal volume, respiratory rate, or inspiratory time (depending on ventilator mode) or increasing flow rate. The pressure time scalar allows the practitioner to view and calculate compliance (Fig. 10-6). Further, one can observe elevations in peak airway pressure that may occur as a result of a large pneumothorax or kinked endotracheal tube or a sharp decrease that may represent an airway leak or disconnection. The volume versus time scalar allows one to identify an airway leak as well (Fig. 10-7). Ventilators often display all three scalars simultaneously. A spontaneously breathing patient is identified by the negative deflection in the pressure–time scalar at breath initiation (Fig. 10-8). Distinct ventilator modes have unique methods of cycling, triggering, and limitations of breaths. In controlled mandatory ventilation, breaths are volume-cycled, time-triggered, and flow-limited (Fig. 10-9). In pressure-controlled ventilation, breaths are time-cycled, time-triggered, and pressure-limited. Note the distinct difference in the flow and pressure versus time scalars compared to CMV (Fig. 10-10). Pressure supported breaths are flow-cycled, patient-triggered, and pressure-limited (Fig. 10-11). Pressure and volume controlled ventilation can be set in an assist control (AC) mode or intermittent mandatory ventilation (IMV) mode. With the AC mode the patient receives a set number of breaths delivered per minute whether with pressure or volume. Patients who initiate breaths on IMV will have tidal volumes determined by their own respiratory effort and not the ventilator. Patients who are critically ill may require AC for full support but these patients should be weaned to an IMV or PSV mode quickly to prevent respiratory muscle atrophy.⁴³

Figure 10-6. Pressure–time scalar.

ACUTE RESPIRATORY FAILURE

Diagnosis

6 Past consensus definitions of adult respiratory distress syndrome (ARDS) and acute lung injury (ALI)

categorized them by acute onset hypoxemia, bilateral infiltrates on chest radiography, and absence of left atrial hypertension (i.e., noncardiac in etiology).⁴⁴ ALI and ARDS were differentiated by the degree of hypoxia, with ALI typified by a ratio of $\text{PaO}_2/\text{FiO}_2$ of less than 300 and ARDS 200. Newer definitions make an attempt at describing timing relative to a known insult and acknowledge that cardiac failure is now often diagnosed without the aid of a pulmonary artery catheter. Most importantly, ALI is now part of ARDS spectrum that is classified as mild, moderate, or severe if the $\text{PaO}_2/\text{FiO}_2$ ratio is between 200 and 300, between 100 and 200, and less than 100, respectively.⁴⁵ Further, this gradation of disease is consistent with therapy, wherein less acute patients might be successfully treated with noninvasive ventilation, moderately ill patients with higher PEEP and possibly neuromuscular blockade, and severely ill patients possibly requiring prone positioning therapy and extracorporeal support.

Figure 10-8. Pressure–time scalar with alternating ventilator-assisted breaths and spontaneous breaths.

Ventilator Management

Conventional Modes

The ventilatory standard of care was set forth as a result of an early study from the NIH ARDS Network. By all metrics, the patients ventilated at 6 mL/kg had better outcome than those who received 12 mL/kg. Thus, as a result, the standard of care for ventilating ARDS patients became the use of low tidal volumes, or low stretch therapy to diminish the incidence of ventilator-associated barotrauma.⁴⁶

Rescue Therapies

Involving different ventilator modes share the fact that they achieve their end by raising mean airway pressure while preventing elevation of peak airway pressure. How the disparate modes of ventilation achieve this varies.

High PEEP. Ideally, to prevent atelectasis and avoid overdistension, PEEP is titrated to the safe window between the lower and upper inflection points of the respiratory pressure–volume curve (Fig. 10-12). The precise PEEP level to optimize outcome from ARDS, particularly in the face of low stretch ventilation, has been the subject of several trials. The Assessment of Low Tidal Volume and Elevated End-Expiratory Pressure to Obviate Lung Injury (ALVEOLI) trial did not demonstrate a benefit to adding high PEEP to those ventilated with lower tidal volumes.⁴⁷ Two other trials (LOVS and EXPRESS) reached similar conclusions.^{48,49} A systematic review and meta-analysis showed no statistically significant difference in hospital mortality overall but worse in those with severe established ARDS treated with high PEEP.⁵⁰

Figure 10-9. Controlled mandatory ventilation. Breaths are volume-cycled, time-triggered, and flow-limited.

Perhaps the more valuable variable to consider preventing barotrauma and atelectasis is not the PEEP level, but rather the transpulmonary pressure. Transpulmonary pressure is the difference between airway pressure and pleural pressure. As airway pressure is normally slightly positive and pleural pressure slightly negative, transpulmonary pressure is typically zero. If transpulmonary pressure were negative, it would favor atelectasis, whereas a positive value would promote barotrauma and hemodynamic compromise. In ICU patients, there are many forces extrinsic to the lung that can raise pleural pressure and promote atelectasis. These include obesity, intra-abdominal hypertension, and anasarca. Thus, in these circumstances, it might be beneficial to utilize higher PEEP levels. Although it is not possible to measure pleural pressure directly, esophageal pressure is a reasonable surrogate. Although titrating PEEP to esophageal pressure has not yet been proven clinically efficacious, it may in the future.

Figure 10-10. Pressure controlled ventilation: Breaths are time-cycled, time-triggered, and pressure-limited.

Figure 10-11. Pressure support (PS). Breaths are flow-cycled, patient-triggered, and pressure-limited. Pressure support breaths are second and fourth breaths.

High-Frequency. Modes include high-frequency jet and oscillatory ventilation. Both utilize ultrafast subtidal ventilation and can be employed for rescue or treatment of bronchopleural fistulae. In general, heavy sedation and/or paralysis are required. The ventilator decouples oxygenation ventilation such that unique settings are used to manipulate either one. The ventilatory circuit is heavy and cumbersome in this mode and secretion clearance is problematic. Importantly, two large trials failed to show improvement in ARDS patients, with one demonstrating an increased mortality in the high-frequency group.^{51,52}

Airway Pressure Release Ventilation (APRV). takes advantage of spontaneous breathing (and hence the ability to keep patients more awake) with CPAP and a brief pressure release, generating a very high inspiratory to expiratory (I:E ratio). The extremely short phase time of pressure release builds up intrinsic PEEP to prevent atelectasis. There are increasing studies in the literature that demonstrate that APRV is at least equivalent to low stretch ventilation in terms of safety and outcome.^{53,54} As APRV may be better tolerated than low tidal volume ventilation, some would say this provides an advantage. There is also some suggestion that routine use of APRV may decrease the incidence of and mortality from ARDS.⁵⁵

Figure 10-12. Pressure-volume curve with added PEEP. V, volume; P, pressure; LIP, lower inflection point; UIP, upper inflection point. Ideal PEEP is set between LIP and UIP.

Volumetric Diffusive Respiration (VDR). Is a hybrid mode that combines convective gas delivery similar to CPAP, diffusive gas delivery similar to oscillatory modes and a unique percussive mode to promote secretion removal. As such, it has been used extensively in the burn patient population. However, the technology is not widely available and large trials of use in rescue therapy of ARDS patients have not been completed.

Extracorporeal Support. via extracorporeal membrane oxygenation (ECMO) was thought to provide a beneficial effect to those patients in the European Conventional Ventilation or ECMO for Severe Adult Respiratory Failure (CESAR) trial.⁵⁶ However, it was apparent on further analysis that patients with

severe ARDS benefit most from transfer to a center that had ECMO capabilities, whether or not the therapy was actually used. Data from recent viral pneumonia epidemics are similarly confusing. Regardless of the effect on mortality, it is apparent that ECMO may be thought of as a last ditch effort to improve oxygenation, but should not be employed after lung fibrosis and irreversible organ failure have transpired. For sure, current technology involving smaller access catheters, more portable oxygenators and venovenous deployment has made ECMO far less morbid than initial experience with it decades ago with prior mortality rates in excess of 50%. The definitive trial without crossover treatment to validate the use of ECMO for severe ARDS has not been performed.

Ventilator Associated Events

Ventilator-associated pneumonia (VAP) is the most common life-threatening healthcare associated infection, although there is some evidence that it is less morbid in surgical than in medical patients.⁵⁷ VAP is associated with increased ICU and hospital length of stay and costs, and may often be preventable. Nonetheless, it can be extraordinarily difficult to define, particularly in injured patients who may be febrile and have pulmonary infiltrates for reasons other than pneumonia. Further, if attempts are made to diagnose the entity predominantly by microbiologic criteria (using bronchoalveolar lavage to culture $>10^5$ organisms), then the incidence of VAP may be overstated. Thus, the CDC has worked with various critical care societies to define the surveillance definition of ventilator-associated events (VAE) which are publically reportable and include probable and possible VAP, which are not reportable. Briefly, VAE require patients to have a baseline period of more than 2 calendar days on the ventilator followed by a sustained decrement in oxygenation. Note there are no longer radiographic criteria for VAE or VAP. An infection-related VAE requires a change in temperature or white blood cell count and the initiation of a new antibiotic that is continued for 4 days. The differentiation between possible and probable VAP involves positive cultures as previously prescribed.⁵⁸

Liberation from Ventilation

Automated, computerized liberation protocols significantly shorten time on ventilator and success rate compared to those directed by physicians. As opposed to the concept of “weaning” patients from support, it is now apparent that the need for ventilation can be approached in a more binomial, on-off approach. Thus, current practice is to complete daily spontaneous breathing trials (SBTs) of no longer than 30 minutes to assess patients’ readiness for liberation from ventilation. Of course, these trials should not be conducted in patients with hypoxia, hemodynamic instability or neurologic disease. SBTs may be accomplished using a T-piece trial or CPAP with or without low PSV (<10 mm Hg), the latter to enable ventilatory monitoring of work of breathing and respiratory effort. If patients develop tachypnea, tachycardia, hypoxia, hypercapnia, and/or use accessory muscles during the SBT they are not ready to be extubated. Typically, the parameter that predicts extubation success most accurately is the rapid shallow breathing index or the tidal volume divided by the respiratory rate with a level of less than 105 most predictive of success.⁵⁹ Further, the requirement for airway support, as might be expected in those with burns, head injury, or anasarca must be considered separately from the requirement for ventilatory support. Checking for a cuff leak, although conceptually of benefit in identifying patients with airway edema, may not be an accurate metric of those with a stable airway. Trials in the medical literature suggest that a short course of steroids may benefit some to diminish airway edema; these have not been replicated in surgical patients.⁶⁰ Finally, some patients, such as those with COPD, may benefit from extubation to noninvasive modes of ventilation such as bilevel positive airway pressure (BiPaP) or CPAP. Additionally, the use of high-flow nasal cannula oxygen, typically delivered at 40 L/min or greater may prevent reintubation.

Adjunctive Therapies

Inhaled Nitric Oxide and Prostaglandins. Inhaled Nitric Oxide (iNO) affords selective vasodilation of the pulmonary vasculature without systemic effect. It improves oxygenation and lowers pulmonary artery pressures. If used, methemoglobinemia can result, thus, monitoring should be conducted. Five early meta-analyses showed improved oxygenation without a mortality benefit, with three demonstrating increased renal failure.⁶¹ A more recent meta-analysis failed to show a mortality advantage for iNO use for mild, moderate, or severe ARDS.⁶² Inhaled and/or intravenous prostacyclins such as epoprostenol can also lower pulmonary artery pressures and improve oxygenation. A 2010 Cochrane review demonstrated no safety or outcome differences between iNO and epoprostenol; however, at present, the latter is substantially cheaper. Although neither agent improves mortality, it

seems reasonable to employ prostaglandins in ARDS patients with concomitant pulmonary hypertension.⁶³

Positional Therapy. Prone positioning therapy can be done in conjunction with many other therapies previously described. It can be accomplished on a conventional ICU bed or one specially equipped to provide this therapy. Either way, extreme caution must be taken to avoid tube and line dislodgement and development of pressure-related skin complications. The ideal amount of time to keep a patient in the prone position is of debate. Often, a patient is turned every shift or if a procedure is required. A recent large study in French ICU patients demonstrated a significant improvement in mortality in ARDS patients treating with prone positioning therapy.⁶⁴ Similarly, a systematic review and meta-analysis reinforced the mortality benefit of nearly 25% by prone positioning therapy for ARDS.⁶⁵

Fluid Management. Another large trial conducted by the ARDSnet group Fluid and Catheter Treatment Trial (FACTT) demonstrated that ARDS patients have better outcome if managed with conservative fluid strategy that need not be guided by a PAC.³⁸ Of course, these findings must be reconciled with extensive data supporting improved outcome in septic patients who received more robust fluid resuscitation.^{66,67}

Steroids. Trials regarding the use of steroids in ARDS are old and heterogeneous. At present, the use of steroids cannot be recommended, but future trials controlling for other factors may indicate otherwise.

Sedation and Paralysis. Recently released pain, agitation, and delirium guidelines underscore several features regarding the sedation of ICU patients. First, most ventilated ICU patients benefit from light sedation and continued emphasis on mobility (even if ventilated) and screening for delirium. If sedative agents are required, a strategy that employs narcotic analgesics first is preferred. If additional agents are necessary, there is substantial evidence that a strategy that relies heavily on use of benzodiazepines will result in a higher incidence of delirium, time on ventilator, and greater costs.⁶⁸ Ideal sedatives should be easy to titrate, short acting with rapid onset, and without accumulation with prolonged use. These sedatives should also have minimal adverse effects, minimal metabolism, and no active metabolites. Traditionally used sedatives and analgesics morphine, propofol, and benzodiazepines have well-known adverse effects, active metabolites and tend to accumulate with prolonged use. Fentanyl is widely used in ventilated surgical ICU patients due to its excellent pain control, rapid onset, short duration of action, and lack of active metabolites. Dexmedetomidine is a sedative with alpha 2-adrenoreceptor agonist properties that is used as an alternative for analgesia and sedation in the surgical ICU. Dexmedetomidine has been shown to decrease the incidence of delirium and decreased duration of mechanical ventilation versus benzodiazepines while not being inferior to benzodiazepines and propofol in maintaining comfort and sedation.⁶⁹ Using sedation scales in the ICU such as the Richmond Agitation-Sedation Scale (RASS) provide a universal numerical scale to communicate between ICU team members the target and actual sedation. Although we should not use long-term neuromuscular blockade (NMB) in those with mild ARDS, a recent French study demonstrated a significant benefit to short-term use in terms of mortality.⁷⁰ A much larger propensity-matched retrospective study documented a 4.3% absolute reduction in mortality with short-term use of NMB in severe ARDS.⁷¹

VENOUS THROMBOEMBOLISM PROPHYLAXIS IN THE ICU

Much attention has been focused on the prevention of venous thromboembolism (VTE) in hospitalized patients, particularly in the United States, Canada, and the United Kingdom where national initiatives are present. VTE prophylaxis is a quality metric promoted by such endeavors as the SCIP discussed elsewhere in this text. The surgical ICU patient is a particular target for VTE and has unique features rendering prophylaxis more challenging than it may be in a ward patient. VTE is a common cause of preventable morbidity and mortality in critical care patients. A large amount of VTE complications occur following surgery and injury.^{12,72} Further, the risk of bleeding in the multitraumatized, immobile, and/or freshly postoperative patient may be heightened in the ICU patient. Finally, safe administration of a chemoprophylactic agent as described below must take into account drug metabolism that may be altered with renal or hepatic failure seen in ICU patients and desire to rapidly reverse the medication if frequent procedures are needed.

Table 10-7A Caprini Risk Assessment for Venous Thromboembolism (VTE) in Surgical Patients

1 Point	2 Points	3 Points	5 Points
41–60 yrs old	61–74 yrs old	>75 yrs old	Hip, pelvis, or leg fracture
BMI >25 kg/m ²	Arthroscopic surgery	PMH of VTE	Elective arthroplasty
Minor surgery	Major open surgery	FH of VTE	Stroke (<1 mo)
Swollen legs	Laparoscopic surgery	Factor V Leiden	Spinal cord injury (<1 mo)
Varicose veins	Malignancy	Prothrombin 20210 A	
Pregnancy/Postpartum	Bed rest >72 hrs	Lupus anticoagulant	
PMH of spontaneous abortion	Immobilizing cast	Anticardiolipin antibodies	
Oral contraceptives/hormone therapy	Central venous access	Elevated serum homocysteine	
Pneumonia (<1 mo)		HIT	
Sepsis (<1 mo)		Other thrombophilia	
Abnormal pulmonary function			
Acute MI			
CHF (<1 mo)			
PMH of inflammatory bowel disease			
Medicine patient on bed rest			

BMI: body mass index, PMH: past medical history, MI: myocardial infarction, CHF: congestive heart failure, FH: family history, HIT: heparin induced thrombocytopenia.

Incidence

The risk for developing asymptomatic lower extremity deep venous thrombosis (DVT) depends on the assessment of general risk factors described below and the type of surgical patient. The incidence can vary from less than 10% (in mobile, thin patients undergoing brief, minor surgery) to over 80% (in those with spinal cord injury or elderly, obese hip fracture patients) in the absence of prophylaxis. However, the true incidence may be unknown. It has become clear that upper extremity DVT (which is not routinely screened) is more common than previously appreciated and may result in pulmonary embolism at a higher rate than thought in the past,⁷³ thus dramatically affecting VTE rates. The incidence of fatal pulmonary embolism in surgical patients ranges from less than 1% in most undergoing elective general surgery to as high as 5% to 8% in those receiving operations for hip fractures.⁷⁴ The projected VTE incidence of the surgical ICU would, thus, depend on the composition and the use of screening for asymptomatic patients.

Risk Factor Scoring

Surgical critical care patients are at increased risk of VTE via Virchow triad of stasis, vessel wall injury, and hypercoagulability. Acquired risk factors in the surgical critical care patients are a consequence of surgery, trauma, immobilization, obesity, malignancy, advanced age, and invasive monitoring devices. The American College of Chest Physicians (ACCP) 2012 guidelines⁷⁵ stratify surgical patients into four risk categories: very low, low, moderate, and high. The most widely used tool to assist in classification is the Caprini score (Table 10-7).⁷⁶ A quick glance at the assessment would reveal that the vast majority of surgical ICU patients over the age of 40 would fall into at least the moderate risk category; if a central venous catheter were present, then they would be considered high risk.

Approaches to Prevention of VTE

Screening – Secondary Prevention

This strategy involves the early detection of subclinical venous thrombosis by regular screening tests. These tests include Duplex ultrasonography and laboratory assays such as evaluation of d-dimer, discussed in further detail elsewhere in this textbook. As most ICU patients will fall into moderate and high risk categories for VTE (in whom d-dimer assays are universally elevated), there is virtually no role for utilizing d-dimer acquisition for diagnostic purposes. Further, although many groups feel differently and perform routine screening lower extremity Duplex ultrasonography, the authors believe that there is little role for this strategy if screening upper extremity studies are not performed concomitantly. Further, as will be discussed below, the safety of early administration of chemoprophylactics is now being proven in even the highest-risk patients (e.g., neurotrauma).⁷⁷

Table 10-7B Caprini VTE Percentage Risk Based on Score

Risk	Score	Estimated VTE Percentage Risk without Prophylaxis
Very Low	0	<0.5%
Low	1–2	1.5%
Moderate	3–4	3%
High	>5	6%

From Caprini JA. Risk assessment as a guide to thrombosis prophylaxis. *Curr Opin Pulm Med* 2010;16:448–452, with permission.

Treatment – Primary Prophylaxis

Interventions for the prevention of VTE include elastic stockings, intermittent pneumatic compression devices, low-dose unfractionated heparin (UFH), low-molecular-weight heparin (LMWH), indirect factor Xa inhibitors such as fondaparinux, direct thrombin and Xa inhibitors, aspirin, and inferior vena cava (IVC) filters.

Mechanical Devices

Alone are utilized for surgical ICU patients at the lowest risk for VTE. Intermittent compression devices may afford additional protection from VTE in those in high-risk groups if used in concert with chemical agents.⁷⁸

Chemical

7 UFH and LMWH. Few studies have performed a head-to-head analysis of these agents for VTE prophylaxis in surgical ICU patients. A study of injured patients completed by Geerts and published in 1996⁷⁹ demonstrated that use of LMWH resulted in a significantly lower incidence of VTE (31% vs. 44%). This likely drove the 2009 ACCP recommendation that moderate and high risk ICU patients should preferentially receive LMWH for prophylaxis (with a IA strength and level of recommendation). However, in the interim, Dr. Geerts and colleagues performed a multicenter, RCT (PROTECT) that did not demonstrate a difference in the development of DVT or proximal DVT in those who received LMWH in the form of dalteparin compared to those administered twice-daily UFH.⁸⁰ There was no difference in bleeding rate, but a higher incidence of PE was noted in the UFH patients (and a nonsignificant increase in heparin induced thrombocytopenia). This study, undoubtedly, drove the 2012 ACCP recommendation that UFH or LMWH can be used interchangeably (2C recommendation).⁷⁵ However, it is vital to mention that the authors excluded injured, orthopedic and neurosurgical patients from this study. Geerts himself provides guidelines suggesting that ICU patients at high risk for VTE including injured and major surgery patients should receive LMWH preferentially. UFH should be reserved for moderate-risk ICU patients. High-risk patients at risk for bleeding should receive mechanical prophylaxis until the risk for bleeding is abrogated, and then LMWH should be initiated.⁸¹ Literature suggests that this may be substantially earlier than we might have thought in the past.⁸² Finally, in those with renal dysfunction, consideration must be given to avoiding LMWH, or at least monitoring Xa levels, although there is little literature to offer guidance in this regard.

Indirect Xa inhibitors include fondaparinux and have been studied extensively in the orthopedic (non-ICU) and general surgery population. In both these populations, it may be more efficacious than LMWH without an increase in bleeding risk.⁷⁵ How this extrapolates to the ICU population is unknown; however, it may be helpful in those with HIT.

There is even less experience using oral Xa (rivaroxaban and apixaban) and thrombin II (dabigatran) inhibitors in the ICU. These agents may be less than helpful because of a long half-life and inability to reverse (particularly dabigatran that may be best removed by hemodialysis). Nonetheless, we should appreciate that all three agents had a lower rate of significant bleeding such as intracranial hemorrhage in outpatients who were being treated for atrial fibrillation. Rivaroxaban is metabolized renally and apixaban both hepatically and renally. Due to similar concerns of time and ability to reverse, the use of aspirin and warfarin may be limited in the ICU.

IVC Filter. At present, the current ACCP guidelines do not recommend insertion of prophylactic IVCF in those who cannot be anticoagulated. They recommend initiating chemoprophylaxis as soon as is practical.⁷⁵

TRANSFUSION OF THE ICU PATIENT

8 Transfusion of packed red blood cells, ostensibly to promote oxygen delivery, is extraordinarily

common in surgical ICU patients. Nearly 85% of those who remain in the SICU after a week and over 40% overall will be transfused, many of whom are not actively bleeding.⁸³ It was reflexive practice a decade or so ago to prescribe a transfusion for ICU patients whose hemoglobin levels fell below 10 g/dL with at least two units being administered. However, packed cell transfusion may not dramatically improve oxygen delivery, particularly in situations where the oxygen dissociation curve has been shifted to the left, as with decreased 2,3-diphosphoglycerate concentrations (Table 10-8). In addition, in many patient populations, transfusion of packed cells has been associated with increased infections and organ failure. The Transfusion requirements in Critical Care (TRICC) trial published in 1999⁸⁴ provided data to question the universal practice of red cell transfusion. This multi-institutional trial of patients in Canadian ICUs was designed as a noninferiority trial comparing a restrictive transfusion strategy, aimed at maintaining a hemoglobin level greater than 7 to 9 g/dL, to a liberal one, targeting a level of 10 to 12. Hebert and colleagues demonstrated no difference in mortality between the groups, the primary outcome measured. Although patients with significant cardiac history were excluded a priori, nearly 300 were studied, and there was no outcome difference in this group either.⁸⁵

Nonetheless, despite widespread dissemination of this landmark article, transfusion practice did not widely change in many surgical ICU patients since and there is still a sense that older, cardiac, actively bleeding, neurosurgical, and septic patients should be excluded from restrictive transfusion practices. However, subsequent studies have further questioned this dogma. A large propensity matched study analyzed the effect of transfusion on ICU patients who were not actively bleeding. It revealed that nontransfused patients (including those with a significant cardiac history) had a lower hospital mortality and incidence of infection and acute kidney injury.⁸⁶ The RELIEVE trial was a multicenter randomized controlled trial of ventilated ICU patients over the age of 55, including one-third with ischemic cardiac disease. Those in the restrictive group received almost a quarter fewer transfusions and had over a 30% lower mortality rate.⁸⁷ A meta-analysis of the effect of blood transfusion during myocardial infarction noted that the therapy was associated with a relative risk of 2.91 for mortality and 2.04 for a subsequent MI with a number to treat of 8.⁸⁸ Further, a British propensity-matched study of cardiac surgery patients revealed odds ratios of 3.8 and 3.5, respectively, for infection and ischemia after transfusion and ratios of 6.69 and 1.32, respectively, for 30-day and 1-year mortality in transfused patients.⁸⁹ This risk of transfusion in cardiac surgery patients is apparent even with administration of small-volume (i.e., one or two units of packed cells) transfusions.⁹⁰ A large, randomized controlled trial of cardiac surgery patients over the age of 18 undergoing a bypass or valve replacement revealed no change in 30-day all-cause mortality or morbidity utilizing a transfusion trigger of 8 versus 10 g/dL of hemoglobin.⁹¹ Further, a large single center study randomized those with severe acute upper gastrointestinal bleeding – almost 75% variceal – to a transfusion target of 7 versus 9 g/dL of hemoglobin. Nearly half of those in the restrictive group did not receive a transfusion and the mean time to endoscopy was 6 hours. The restrictive group had a 45% relative reduction in mortality and all adverse events, mostly confined to those in Child’s groups A and B (there was no difference in those in Child’s C classification group). This study reinforced the findings of a previous observation study that a liberal transfusion target in active upper gastrointestinal bleeding doubled the risk of rebleeding and increased mortality by 28%,⁹² presumably by promoting “popping the clot.” In a randomized clinical trial of patients with traumatic brain injury, a hemoglobin target of 10 compared to 7 g/dL was associated with no improvement in neurologic outcome at 6 months but a higher incidence of adverse events including thromboembolism.⁹³ Finally, in a multicenter, RCT of septic patients, a hemoglobin target of 7 g/dL with transfusion of leukoreduced cells was not associated with difference in 90-day hospital mortality of adverse events compared to 1 of 9 g/dL.⁹⁴

Table 10-8 Factors Altering the Oxygen Dissociation Curve

Left Shift	Right Shift
Decreased temperature	Increased temperature
Decreased 2,3-DPG	Increased 2,3-DPG
Increased pH	Decreased pH
High altitude, Carbon monoxide	

Oxygen dissociation curve describes how our blood carries and releases oxygen. Right shift represents a decreased affinity for oxygen by hemoglobin favoring to the ability to release oxygen to tissues in need. Left shift represents increased affinity by hemoglobin for oxygen 2,3-DPG: 2,3-diphosphoglycerate.

Although administration of both erythropoietin⁹⁵ and intravenous iron⁹⁶ would seem sound practice

to mitigate against transfusion and the harmful effects thereof, in clinical practice in the SICU, neither has been effective in dramatically impacting transfusions or outcomes. It may be most prudent to “ride out” the anemia seen in ICU patients, minimize unnecessary blood draws, and improve oxygen delivery by other means (although they, too, have not afforded improved outcomes).

METABOLISM AND NUTRITION

Classic texts on surgical nutrition emphasize the metabolic and hormonal differences between the states of starvation, one of decreased metabolic rate, and that of stress, one of increased metabolism driven by so-called stress hormones. In reality, many surgical and trauma patients experience stress after a fast, although the use of early nutrition in almost all has largely prevented this.

In starvation, fat oxidation is the principle energy source after glycogen stores are exhausted within 24 hours. Patients turn to gluconeogenesis (particularly in cells that are obligate glucose users such as neurons and red blood cells) for fuel, resulting in increased free fatty acids, ketones, and glycerol. This amplified gluconeogenesis results in exhaustion of amino acid levels and protein wasting. Eventually, glucose levels drop as does insulin. Stress hormones, including cortisol and catecholamines, promote protein catabolism. As glucose is used up, a switch is made to fat metabolism with the inability to keep up via gluconeogenesis.

Critically ill patients are in a catabolic stress state with a systemic inflammatory response. Malnutrition in critically ill patients leads to worse outcomes; inability to wean from the ventilator, pressure ulcers, and increased risk of infectious complications. For these reasons, it is critical that ICU patients undergo assessment and adequate support of their nutritional status. Goals of nutrition support are to preserve lean body mass, maintain immune function, and avert metabolic complications.^{1,97}

Metabolic Requirements and Assessment

Metabolic requirements for ICU patients for both calories and protein needs are based on ideal body weight. Equations, such as the Harris–Benedict calculation, can assist in determination of caloric administration and are based on the patient’s baseline energy expenditure, referred to as the basal metabolic rate (BMR) and/or basal energy expenditure (BEE). BMR is the estimated rate of energy used by the body at rest and is only sufficient for the functioning of vital organs. The BEE varies with age, lean body mass, and sex. In most circumstances, ICU patients should receive 25 to 30 kcal/kg/day and 1.2 to 2.5 g/kg/day of protein (highest in stressed burn patients). In fact, hypocaloric, high-protein diets may be best for many, if not most, ICU patients. Starting critically ill patients at 8 to 10 kcal/kg/day and attempting to achieve goal nutrition of 25 to 30 kcal/kg/day within a week is optimal.⁹⁸

The most important nutritional assessment of our ICU patients is the least high tech – that is, a careful history and physical examination documenting diet status, weight loss, and the nature of the operation or trauma. We often supplement this with quantitative assessment of protein and caloric adequacy. These include simple laboratory tests and more complicated evaluations. A variety of visceral proteins with relatively short half-lives have been assayed for their relation to protein status. These include prealbumin, transferrin, and retinol-binding protein (with half-lives of 2, 8, and 10 days, respectively) as opposed to albumin whose half-life is 21 days. However, even prealbumin levels may respond to factors other than nutritional status, including ongoing inflammation. The most accurate assessment is via indirect calorimetry. This allows for the direct measurement of oxygen consumption (VO_2). It is best determined in those on stable ventilator settings with an inspired oxygen fraction of less than 65% and no airway leaks. However, use of indirect calorimetry to guide nutritional support has not been demonstrated to result in improved outcomes to justify its expense.

Energy Sources

Carbohydrates, fat, and protein each contain a unique amount of calories per gram and respiratory quotients (RQ), a ratio of CO_2 consumption (VCO_2) over oxygen consumption (VO_2). Ratios that exceed one will result in the body’s need to eliminate additional CO_2 , which can be of consequence in those on ventilator support with lung disease. The goal of ICU nutrition is to provide energy from carbohydrate and fat sources, so that exogenous proteins can be used for anabolism and not catabolism. This principle is the protein sparing effect of carbohydrate and fat administration. Less than 500 kcal/day are protein sparing, although in most instances, we provide many more calories with traditional ICU nutrition.

Carbohydrates provide 3.4 kcal/g and have the highest RQ of 1.0. Thus, excess carbohydrate calories can result in prolonged ventilator needs. An RQ of greater than one is seen with glycogen storage. The ICU patient should be provided with 5 to 6 g/kg/day of carbohydrates.

Fat provides 9.0 kcal/g with an RQ of 0.7. ICU patients should receive 1 g/kg/day or less of fat. Fat deficiency used to be fairly common in ICU patients before early and adequate nutrition. Deficiency can result in anemia, thrombocytopenia, respiratory distress, and rash. Excess fat can promote cholestasis and fatty liver resulting in coagulopathy. In fact, it is possible to administer nearly all of one's nonprotein calories as carbohydrates, providing essential fatty acids are administered. However, this would result in an increased RQ (with ventilatory consequences) and issues of glycemic control. Fatty acids exist in two varieties, omega-three and omega-six. Omega-three fatty acids are derived from linolenic acid, found in fatty fish such as salmon, and are less pathogenic than omega-six fatty acids derived from linoleic acid. In stress, after the body exhausts its supply of carbohydrates, it relies on lipolysis which lowers the RQ (until the supply of fatty acids is also consumed and proteolysis occurs).

Protein delivers 4.0 kcal/g with an RQ of 0.8. Essential amino acids cannot be synthesized endogenously and must be provided in the diet and include: methionine, threonine, tryptophan, valine, phenylalanine, isoleucine, leucine, lysine, and histidine. Diets specialized for those with renal failure deliver their protein in the form of essential amino acids. Semiessential amino acids such as arginine and glutamine are difficult for the body to manufacture in times of stress and are obligately utilized by certain cell types. Protein is the important component of nutrition due to the body's obligate synthetic needs. We are able to measure the efficacy of protein nutrition by assaying nitrogen balance – a balance sheet between protein in and nitrogen out measured in the urine. This, of course, requires that we remember that a gram of protein contains 6.25 g of nitrogen. Severely burned patients can lose 25 g N (125 g pro) daily. In certain conditions, such as sepsis, we may not be able to provide enough protein to avoid negative nitrogen balance.

Vitamins and minerals. Contemporary supplemental nutrition contains sufficient trace elements and vitamins to make deficiency in ICU patients a thing of the past in most instances. A resurgence in this has occurred with the care of bariatric patients and the deficiencies they experience post bypass, most notably of thiamine. Interesting to note, virtually all enteral formulae contain vitamin K – some in rather large amounts – so anticoagulation may be difficult (Table 10-9).

The nutritional support of the malnourished and nourished patient employs different strategies to optimize outcome. Malnourished patients may benefit from preoperative nutritional support for at least 7 days that can be delivered enterally, if possible. Well-nourished patients should have nutrition resumed within 48 hours; however, it is safe, if not wise to delay parenteral nutrition for 5 to 7 days if the enteral route is not possible. There is much controversy and regional variability regarding this issue with the Europeans preferring earlier initiation of parenteral nutrition, as will be discussed below.

Enteral Nutrition

9 In general, enteral nutrition should be used early and often in ICU patients. Standard enteral formulas include fatty acids, carbohydrates, protein, vitamins, minerals, and micronutrients. A standard formula is isotonic to serum and has a calorie density of 1 kcal/mL. A concentrated formula is used in patients who may benefit from low volume nutrition. Concentrated formula is hyperosmolar with a calorie density of 1.2 to 2.0 kcal/mL. There are specific formulations that address types of organ dysfunction. So-called pulmonary formulations are low in carbohydrates; renal formulas are concentrated with essential amino acids and hepatic formulas contain branched chain amino acids. Further, enteral feeds are either polymeric or elemental – that is, broken down to the basic building blocks of the energy substrates – proteins as free amino acids, fats as medium chain triglycerides, and carbohydrates as oligosaccharides at a calorie concentrations of 1 to 1.5 kcal/mL. Elemental feeds may be useful in the stressed patient as they require minimal intraluminal digestion. Elemental formulas should be considered in patients with nutrition absorption disorders and those that fail to tolerate standard enteral nutrition.

Table 10-9 Vitamin Deficiencies

Vitamin	Deficiency
A	Blindness and conjunctival spots (Bitot's)
D	Rickets and osteomalacia
E	Newborn anemia, neuropathy, and hemolysis
K	Bleeding
B1	Beriberi: weakness, CHF, lactic acidosis
B2	Tongue changes, photophobia
B6	Neuropathy, seizures, anemia, and glossitis
B12	Anemia, weakness, optic/MS changes
B3	Pellagra: dementia, diarrhea, and dermatitis
Folate	Diarrhea and anemia
C	Bleeding, petechiae, scurvy, and wound healing abnormalities

There are several complications related to enteral nutrition in the ICU, the most significant of which is aspiration. To decrease the aspiration risk, the ICU staff should maintain head-of-bed elevation at 45 degrees or greater and consider promotility agents. Regular assay of gastric residuals may not decrease aspiration risk.⁹⁹

Parenteral nutrition requires the insertion of a central catheter or a centrally directed peripheral one. As such, the complications of parenteral nutrition include the risks of catheter insertion and infection in addition to the metabolic consequences of feeding (such as hyperglycemia) that can also be seen with enteral nutrition. Parenteral nutrition can be prepared in standard or concentrated formulations depending upon the glucose with added amino acids and fat. There may be evidence that hypocaloric formulas with limitation of fat early on are beneficial.⁹⁷

Immunonutrition

In addition to use of omega-three fatty acids, there are other ingredients that may be helpful to use in the stressed patient. In small, early nonrandomized trials, semiessential amino acids arginine and glutamine have been shown to be beneficial and the use of high-protein/low-calorie strategies may be most optimal, particularly using branched chain amino acids. There was thought to be a notable exception to this strategy – arginine, in particular, was not advised in the patient who is already infected.¹⁰⁰ Arginine is metabolized to nitric oxide which may increase permeability, hemodynamic instability, and translocation in septic patients. However, this may be mitigated by increased production of arginase in septic patients. Increasing literature actually supports increased perfusion by giving arginine in sepsis.^{101,102} Thus, arginine administration is likely safe in sepsis, but the preferred dose is still of debate. Glutamine is rapidly depleted from muscle stores and thought to be important in minimizing translocation as it assists in maintaining gut barrier function as an enterocyte fuel. A hypocaloric, high-protein strategy appears to be most beneficial with a calorie to nitrogen ratio of 100–150:1 compare to the more traditional 300:1. However, large randomized trials discussed below question the clinical efficacy of immunonutrition.

Controversial Issues in ICU Nutrition

Delivery of Early Enteral Nutrition

Most critically ill patients are unable to ingest enteral nutrition and have a need for access to the enteric track. There is no compelling evidence that enteral feeds need be delivered in a specific location – that is, there is little data to suggest that postpyloric feeding results in lower aspiration rates or in better food tolerance with higher caloric provision.¹⁰³ Gastric tube feeding is the most common method to deliver enteric nutrition. Via an orogastric or nasogastric route, sump tubes or smaller-caliber feeding tubes are placed into the stomach with confirmation by abdominal x-ray. Surgically placed gastric feeding tubes, whether placed percutaneous or via an open procedure, can also be used for a more long-term enteral nutrition access. Postpyloric tube feeding should be considered in patients who cannot tolerate gastric enteral nutrition or patients who have undergone surgical procedures that have altered anatomy. Placement of a postpyloric tube can be done with blind placement via the nasal or oral route. These tubes may also be placed via open surgical procedures with a single tube inserted directly in the intestine distal to the pylorus or with a tube with a port to drain the stomach and a distal port to deliver enteral nutrition into the duodenum. Postpyloric placement of enteral nutrition access has no benefit over gastric feeding access in terms of energy delivered or rate of aspiration pneumonia, and so it is recommended to proceed with enteral nutrition via the gastric route.¹⁰³

Perioperative delivery of enteral nutrition may be challenging in certain circumstances. However, lessons learned in burn patients reinforce the notion that continuous feeding for nonabdominal procedures is safe.¹⁰⁴ Similarly, presence of an open abdomen is not a contraindication to provision of enteral nutrition.¹⁰⁵

Compared to intravenous dextrose or no nutrition, early enteral nutrition results in lower morbidity (largely infectious), mortality, and cost in ICU patients.^{106–108} Bowel rest is not beneficial in ICU patients. Just as asystole does not rest the heart, starvation does not inhibit bowel function, rather it decreases splanchnic flow and results in bacterial overgrowth and translocation. Enteral nutrition promotes blood flow, arguing against the routine practice of discontinuing it in those on pressors.^{109,110}

There is some sense that if full feeding is not possible for whatever reason, that partial or trophic nutrition be employed. This strategy aims to prevent the overgrowth of bacteria in a static gastrointestinal tract that could result in translocation into the portal circulation causing sepsis and fueling multiple organ failure. However, the EDEN study comparing the use of trophic versus full feeding in ARDS patients did not demonstrate a benefit to the former in terms of infection rate, ventilator days, ICU length of stay, or mortality. Of course, this study does not address what one should do if full feeds are not possible – maintain trophic only enteral feeds, add partial or full parenteral feeds, or employ another strategy.¹¹⁰ Earlier enteral versus parenteral nutrition studies were fraught with issues of overfeeding, imprecise glucose control, and the potential for substandard intravenous catheter care, all of which would raise the risk of infection in those parenterally fed.

Strategies When Unable to Feed Enterally/Role of Supplemental Parenteral Nutrition

Several recent studies have addressed the role of supplemental parenteral nutrition to be used in instances when enteral nutrition might not be possible. In the large EPaNIC study from Europe of over 4,000 patients randomized to “early” or “late” parenteral nutrition if caloric goals were not met by day 2, early patients did worse. Those randomized to receiving late parenteral nutrition (by day 7) had shorter ICU and hospital length of stay, fewer infections, less ventilator and dialysis days, and lower cost. The more parenteral nutrition patients received, the worse the outcome.¹¹¹ In a large Australian randomized trial, the only parameter that was improved by supplemental parenteral nutrition was a clinically insignificant, but statistically significant, difference in ventilator days (less than one half day).¹¹² The Swiss SPN study of supplemental parenteral nutrition demonstrated no difference in mortality, infections to day 28, length of stay or ventilator days between groups.¹¹³ In injured patients, the use of parenteral nutrition has largely been abandoned, used in fewer than 5% of patients in one study. Supplemental parenteral nutrition in a cohort of severely blunt injured patients doubled both the rate of infections and mortality.¹¹² Finally, a recent randomized controlled multicenter trial – CALORIES – compares the use of early enteral and parenteral nutrition. Interestingly, the authors found no difference in the infection rate, adverse events, or mortality.¹¹⁴ While some can interpret this study as one that supports the safety of early parenteral nutrition, an alternate view would be that less expensive early enteral nutrition is, in fact, able to be administered in most ICU patients.

Delivery of Immunitrition

Glutamine and omega-three fatty acids (fish oils). Previous retrospective studies of immune modulating nutrients such as glutamine, selenium, and omega-three fatty acids indicated an outcome benefit in terms of diminished infections and improved survival using high-protein enteral formulas. However, newer studies are not as conclusive. In the REDOXS trial examining the effect of supplemental intravenous or oral glutamine in septic patients with multiple organ failure, glutamine administration resulted in an increased mortality rate of over 5%.¹¹⁵

There is not convincing evidence that utilizing an omega-three-rich lipid composition in parenteral nutrition affects mortality or ICU length of stay,^{116,117} but this may be a function of route delivered and baseline nutritional status. It's not clear that there is a benefit for enteral administration either, with some showing great benefit while others do not. Finally, the recent MetaPlus study described a multicenter, randomized, double-blind trial of 301 mechanically ventilated adult patients using comprehensive immunonutrition. There was no difference reported in infection rate, ventilator days, and ICU and hospital length of stay between groups. Further, although not seen in trauma and surgical patients, in this study, immunonutrition was associated with substantially higher 6-month mortality (54 vs. 35%) in medical ICU patients.¹¹⁸

Nutrition for Specific Indications

Acute Pancreatitis

Enteral nutrition, if possible, is preferable in acute pancreatitis as it decreases length of stay, improves resolution of SIRS, decreases infection rate, and does not stimulate exocrine pancreatic secretion to a great extent. A recent Cochrane review of eight trials revealed a relative risk of death of 0.18 and 0.46 for multiple organ failure for those with severe acute pancreatitis who received enteral nutrition.¹¹⁹

Obesity

Goals in management of the obese patient are to reduce fat mass, improve insulin sensitivity, and preserve lean body mass. A high-protein, hypocaloric strategy is favored with 22 to 25 kcal/kg/day based on ideal body weight and 2.0 to 2.5 g/kg/day of protein.

Stress Gastrointestinal Bleeding Prophylaxis

Endoscopic evidence of upper gastrointestinal bleeding is extraordinarily common in ICU patients. It is present shortly after admission in high-acuity ICU patients and thought due to impaired mucosal protection and less so due to acid hypersecretion and *Helicobacter pylori* infection. The latter two are features typical of more distal ulcers that can also result in upper gastrointestinal bleeding. Overt bleeding, manifested by coffee ground upper intestinal aspirates or hemocult positive stool, is appreciated in up to 25% of patients in the ICU. Clinically significant bleeding resulting in the need for a blood transfusion and/or hemodynamic instability is much less common, noted in less than 5% of ICU patients, with or without pharmacologic prophylaxis. The strongest risk factor for stress gastrointestinal bleeding in the ICU is the need for more than 48 hours of mechanical ventilation, although epidemiologic studies pointing to this observation are dated.¹²⁰ The next most common risk factor is the presence of coagulopathy. It seems prudent that pharmacologic prophylaxis of stress gastrointestinal bleeding in ICU patients be limited to those with these two risk factors. There may, however, be a role to avoid pharmacologic agents even in the highest-risk patients, particularly if they are being enterally fed.¹²¹ If pharmacologic prophylaxis is prescribed, proton pump inhibitors (PPI's) appear to be superior to histamine-2 receptor antagonists in diminishing gastrointestinal bleeding; however, there is no change in mortality, length of stay, or pneumonia incidence in ICU patients.¹²² However, PPI's increase the risk for infection with *Clostridium difficile*, although this association has not been appreciated in ICU patients to date.

ACUTE KIDNEY INSUFFICIENCY (AKI)

Acute renal failure complicates at least 5% and as many as 30% of all surgical ICU admissions with a mortality of over 50%, as the most prognostic component of multiple organ failure. In analysis of a cohort of hypotensive, severely blunt injured patients enrolled in the "Inflammation and the Host Response to Injury" (Glue Grant) database, AKI occurred in one-quarter of patients with a threefold adjusted risk for hospital death.¹²³ AKI can be graded along a spectrum as described by the RIFLE classification (from risk to injury to failure to loss to end-stage kidney disease) as defined by the Acute Dialysis Quality Initiative (ADQI), and may be oliguric or nonoliguric (urine output < or > 400 mL/day in adults). Oliguric renal failure and higher grades of injury portend a higher mortality. An additional classification system has been developed by the Acute Kidney Injury Network (AKIN) and is also composed of urine output and serum creatinine criteria as described in Table 10-10. AKIN has the advantage of considering minor variations in serum creatinine better than does RIFLE and it avoids interpretation errors in the absence of a baseline creatinine value. Neither classification system, however, is favored in terms of predicating incidence of and outcome from AKI. However, to simplify matters, the Kidney Disease Improving Global Outcomes (KDIGO) work group recently proposed a hybrid definition.¹²⁴⁻¹²⁶

Etiology

Acute kidney injury and ultimately failure is the result of forces extrinsic to the kidney or inherently parenchymal (about 90%). Prerenal versus postrenal causes can be distinguished with serum and urine osmolality and basic metabolic panel measurements (Table 10-11). Radiographic diagnostic studies (i.e., ultrasound and CT scan) can diagnose hydronephrosis or a distended bladder as causes of postrenal AKI. Prerenal azotemia, in which the kidney perceives a lack of perfusion, may occur with both hypovolemia and hypervolemia, the latter with congestive heart failure and impaired cardiac function. Initially, the kidney is able to maintain perfusion by selectively dilating the afferent arteriole and vasoconstricting the efferent arteriole of the juxtaglomerular apparatus. As hypotension persists and the renin-

angiotensin system is activated, systemic vasoconstriction occurs and cortical hypoperfusion occurs. It is important to note that laboratory markers are able to distinguish between prerenal and renal causes of AKI, but not between hypovolemic and hypervolemic/cardiogenic states that may be the proximal cause.

Table 10-10 RIFLE AKIN and KDIGO Classification of Renal Failure

RIFLE Classification of Renal Failure		
Stage	GFR	Urine Output
R – Risk renal injury	Baseline Cr $\times$ 1.5 Decrease GFR $>25\%$	UO <0.5 mL/kg/hr $\times$ 6 hrs
I – Injury to kidney	Baseline Cr $\times$ 2 Decrease GFR $>50\%$	UO <0.5 mL/kg/hr $\times$ 12 hrs
F – Renal Failure	Baseline Cr $\times$ 3 Cr >4 mg/dL with increase of 0.0 mg/dL Decrease GFR $>75\%$	UO <0.3 mL/kg/hr $\times$ 24 hrs anuria $\times$ 12 hr
L – Loss of renal function	Persistent renal failure Loss of renal function >4 wks	
E – ESRD	Renal failure >3 mo	
Acute Kidney Injury Network (AKIN) Classification of Acute Kidney Injury		
Stage	GFR	Urine Output
1	Baseline Cr $\times$ 1.5–2 Increase >0.3 mg/dL in 48 hrs	UO <0.5 mL/kg/hr $\times$ 6 hrs
2	Baseline Cr $\times$ 2–3	UO <0.5 mL/kg/hr $\times$ 12 hrs
3	Baseline Cr $\times$ 3 Cr >4 mg/dL with acute increase 0.5 mg/dL Renal replacement therapy	UO <0.3 mL/kg/hr $\times$ 24 hrs Anuria $\times$ 12 hrs
Kidney Disease Improving Global Outcomes (KDIGO) Staging of AKI		
Stage	Serum Creatinine	Urine Output
1	Baseline $\times$ 1.5–1.9 Increase >0.3 mg/dL	<0.5 mL/kg/hr for 6–12 hrs
2	Baseline $\times$ 2–2.9	<0.5 mL/kg/hr for >12 hrs
3	Baseline $\times$ 3 Increase >4 mg/dL Initiation of renal replacement therapy <18 -yr-old decreased GFR <35 mL/min per 1.73 m ²	<0.3 mL/kg/hr for 24 hrs Anuria >12 hrs

ESRD: end stage renal disease, GFR: glomerular filtration rate, Cr: creatinine, UO: urine output.

Table 10-11 Prerenal Versus Acute Tubular Necrosis as the Cause for Acute Kidney Injury

Diagnostic Study	Prerenal	Acute Tubular Necrosis
Urinalysis	Normal	Casts and epithelial cells
Serum BUN:Cr	20:1	Normal
Urine osmolality	>500 mOsm/kg	<350 – 450 mOsm/kg
FENa	$<1\%$	$>2\%$

BUN: blood urea nitrogen, Cr: creatinine, FENa: fractional excretion of sodium; mOsm: milliosmole.

Acute tubular necrosis (ATN) results as a consequence of ischemia (most) or nephrotoxic agents. The former may occur in the face of sepsis, hypovolemia, or cardiogenic shock. The latter includes common ICU medications, radiocontrast media, or pigments (myoglobin and hemoglobin). Medications that may cause ATN include aminoglycosides, cephalosporins, amphotericin, and cisplatin. Contrast nephropathy occurs in about 5% of those exposed; particularly at high risk are elderly diabetics with pre-existing kidney disease. Rarely will patients with contrast nephropathy progress to requiring dialysis. Only administration of intravenous saline precontrast administration has been demonstrated to lessen the incidence of contrast nephropathy.¹²⁷ The use of n-acetyl cysteine or bicarbonate has not been beneficial. In those with pre-existing renal insufficiency who nonetheless require administration of contrast media, there may be a role for prophylactic continuous dialysis. Hemoglobin pigment rarely causes ATN in surgical ICU patients. A rare but morbid cause would be the administration of incorrectly crossmatched blood products. Myoglobinuria as a consequence of rhabdomyolysis is far more common in the ICU and occurs after severe trauma, compartment syndrome, electrical burns, seizures, or coma

with prolonged immobilization. Myoglobinuria should be suspected in patients with dark urine and a positive urine dipstick without red cells on microscopy. Patients with a serum myoglobin level exceeding 10,000 ng/mL or a creatinine phosphokinase (CPK) greater than 20,000 IU/L are at risk for pigment nephropathy. Myoglobin is both a potent vasoconstrictor (FeNa is <1%) and a direct tubular toxin when converted to ferrihemate in an acid environment. However, alkalinization of the urine (with administration of sodium bicarbonate) has not been proven to be more effective than volume administration and forced diuresis to achieve a urine output of 2 mL/kg/hr.¹²⁸

Postobstructive uropathy is rare in the ICU and leads to AKI as the result of a mechanical obstruction to urinary flow. An obstructed urinary catheter is the most common cause and should prompt ICU personnel caring for a patient with an abrupt cessation of urinary output to interrogate the patency of the catheter.

10 Prevention of acute renal failure is most effectively achieved by controlled fluid resuscitation of volume repletion. There is little evidence to benefit of colloid over crystalloids. Higher-molecular-weight hydroethyl starch preparations should be avoided, however, as they are nephrotoxic through tubular obstruction. If a mean arterial pressure (MAP) of greater than 65 mm Hg cannot be maintained solely with fluid administration, it is reasonable to initiate norepinephrine therapy. There is no role for the use of low-dose dopamine for protection against AKI or improvement of diuresis, as noted by several meta-analyses.^{129,130}

Treatment of Acute Renal Failure

General Care

Attention must be directed toward management of electrolyte disturbances and hypervolemia in those with renal failure or impending failure. Hyperkalemia, hyperphosphatemia, metabolic acidosis, uremia, and congestive heart failure may all be of consequence. It is important to remember that treatment for hyperkalemia can either be temporizing or definitive. Temporizing treatment such as the administration of calcium or insulin will stabilize cell membranes and lessen cardiac irritability by forcing potassium intracellularly. However, only removal of potassium through the gastrointestinal tract, the urine or dialysis offers definitive therapy. Thus, if a surgical ICU patient is oliguric and not a candidate for enteral or rectal administration of a potassium binder, then dialysis must be promptly administered to those with markedly elevated potassium levels or ECG changes. Similarly, uremia causing a significant pericardial effusion or encephalopathy may be temporized or treated definitively with dialysis. Platelet dysfunction is also associated with AKI, particularly in face of a BUN in excess of 100 mg/dL. The administration of desmopressin (DDAVP) or analogues may be of benefit. Finally, as the strategy for renal replacement therapy is developed, attention must be directed toward optimizing nutritional status without worsening electrolyte disturbances or hypervolemia. Prior to initiation of dialysis, it may be necessary to limit protein administration so as to avoid exacerbating uremia. However, as renal failure typically occurs in the catabolic milieu of multiple organ failure, it is vital to administer an adequate protein substrate as well as calories to prevent excessive gluconeogenesis and protein breakdown. This, in turn, leads to worsening uremia.

Diuretics

There may be a theoretical attraction to using diuretics to ameliorate AKI. However, in practice diuretics have not been successful in either preventing or ameliorating AKI. Rather, prophylactic diuretics often raise serum creatinine levels. Systematic reviews and meta-analyses^{131,132} have demonstrated that diuretic use does not alter outcome from AKI, but has a significant risk of morbidity (such as hearing loss) and even mortality in some. Finally, if diuretics are used, there is no evidence in systematic review and meta-analysis that continuous dosing is superior to bolus administration.^{133,134}

Renal replacement therapy (RRT) is indicated for intractable fluid overload, hyperkalemia (potassium concentration greater than 6.5 mmol/L or 5.5 with ECG changes), severe metabolic acidosis (pH <7.1), uremic encephalopathy or pericarditis and overdose with a dialyzable agent. Hemodialysis is typically performed in ICU patients and may be continuous or intermittent. Both the Randomized Evaluation of Normal versus Augmented Level Renal Replacement (RENAL) study and the Veterans Administration/National Institutes of Health Acute Renal Failure Trial Network (ATN) failed to demonstrate a benefit from increasing the intensity of RRT beyond 20 to 25 mL/kg/hr of effluent flow, the former trial utilizing continuous modes, the latter intermittent.^{135,136}

Continuous renal replacement therapy (CRRT) includes slow continuous ultrafiltration (SCUF) and continuous venovenous and arteriovenous modes. Patients who are placed on CRRT must have a

temporary double lumen dialysis catheter placed in the internal jugular, femoral, or subclavian vein (in order of preference). Once the dialysis catheter is inserted, the blood flow through the filter is moved by a peristaltic pump. SCUF is utilized exclusively for volume removal which can be achieved at up to 2 L/hr. No replacement fluid is used, thus, there is minimal clearance of toxins. Arteriovenous circuits, employing the patient's own perfusion pressure to drive the system, are rarely used currently. Rather a pump is used to drive a continuous venovenous circuit that can provide hemofiltration, hemodialysis, or, most often, both. Continuous venovenous hemofiltration (CVVH) uses replacement fluid in the same direction as the blood flow to dilute toxins in plasma as the toxins are removed with the ultrafiltrate. Clearance of toxins is through the process of convection based on particle size where small, medium, and large molecules are sieved out across a pressure gradient. Thus, electrolytes are leached out and replacement fluid is warranted. Continuous venovenous hemodialysis (CVVHD) uses a dialysate that flows through the filter in the opposite direction of blood flow (and no replacement fluid) to remove toxic waste and fluid of small molecules (such as urea) through the process of diffusion across a concentration gradient. Finally, continuous venovenous hemodiafiltration (CVVHDF) combines both convection and diffusion through a high-permeability membrane, using both dialysate and replacement fluids. In those at a high risk of bleeding, it is reasonable to consider citrate anticoagulation (in the absence of liver failure) or no anticoagulation with predilution administration of replacement fluids. In those with moderate bleeding risk and/or frequent filter clotting, low-dose unfractionated heparin or LMWH should be administered or argatroban in those with heparin-induced thrombocytopenia. The use of CRRT may be preferred in those with brain edema, persistent metabolic acidosis, large fluid removal requirements, and severe hemodynamic instability although hybrid modes, described below, may play a role. Most patients have optimal clearance and treatment with running CRRT at 30 mL/kg/hr.¹³⁷ There has been some discussion about using high flow CRRT (70 mL/kg/hr) for the treatment of sepsis. In patients with severe sepsis or septic shock without renal failure, there is no role for high volume hemofiltration as reinforced in a recent multicenter study, the high volume in intensive care (IVOIRE) trial.¹³⁸

Intermittent hemodialysis (IHD) is performed at high flow rates (> 300 mL/min) in a short session relying on diffusion to clear toxins. Although it is thought that IHD is contraindicated in the face of hemodynamic instability, it is possible to utilize this mode. Sufficient data do not exist to determine which dialysis mode is optimal in promoting eventual renal recovery. Analysis suggesting a lower rate of recovery with IHD relies heavily on data from older observational trials.^{139,140}

Hybrid modes include sustained low efficiency dialysis (SLED). This can be thought of as stretching out an intermittent dialysis session to promote improved hemodynamic stability and take advantage of the cost benefits of IHD. SLED uses a conventional hemodialysis machine over 8 to 12 hours with lower blood and dialysate flow rates. Various strategies exist to improve hemodynamic tolerance.

ENDOCRINE ISSUES IN THE ICU

Glucose Control

11 Hyperglycemia is common in critically ill patients and associated with poor clinical outcomes. Critically ill patients are hypermetabolic due to elevated cortisol, growth hormone and catecholamine levels, leading to increased hepatic gluconeogenesis, insulin resistance and hyperglycemia. Since critically ill patients with hyperglycemia have increased mortality and complications including infection and worse neurologic outcomes, assiduous glucose control has been practiced in critically ill hyperglycemic patients.^{141,142} However, the optimal blood glucose range is controversial. Intensive insulin therapy (IIT) typically employs continuous insulin infusions to maintain glucose levels of 80 to 110 mg/dL. Conventional blood glucose therapy could utilize either bolus or continuous insulin to maintain glucose levels at a higher range. The Leuven surgical trial of mostly cardiac surgery patients provided the groundwork for the use of IIT. One thousand five hundred and forty-eight patients were randomized to IIT with infusion insulin versus conventional glucose management of 180 to 200 mg/dL. IIT resulted in lower ICU and hospital mortality (4.6% and 7.2% vs. 8% and 10.9%, respectively), renal failure, transfusion requirement, blood stream infections, and critical illness neuropathy, with more frequent hypoglycemia.¹⁴³ Other trials that included surgical patients reached opposite conclusions. The Volume Substitution and Insulin Therapy in Severe Sepsis (VISEP) trial was a multicenter trial that was stopped early because of the increased rate of hypoglycemia and serious adverse events in the IIT group without a difference in mortality.¹⁴⁴ Similarly, the multicenter Glucontrol trial was terminated early

because of the high rate of hypoglycemia in the IIT group.¹⁴⁵ The largest trial, Normoglycemic in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation (NICE – SUGAR) included over 6,000 medical and surgical ICU patients randomized to IIT with blood glucose targets of 81 to 108 mg/dL and conventional blood glucose targets of <180 mg/dL. The IIT group had decreased mean blood glucose levels, significantly higher mortality and more incidence of severe hypoglycemia.¹⁴⁶ Current guidelines recommend moderate blood glucose control of 144 to 180 mg/dL for critically ill patients to avoid both marked hyperglycemia and iatrogenic hypoglycemia.¹⁴⁷ This can be achieved predominantly by avoiding the use of glucose-containing intravenous fluids to avoid the need for insulin administration. If insulin is needed, continuous infusions and intermittent short-acting agents may be safer in ICU patients.

Adrenal Insufficiency

Absolute **adrenal insufficiency** is rare in critically ill patients, with an incidence estimated at less than 5%.¹⁴⁸ Relative adrenal insufficiency, manifested by hypotension and fever (and rarely with electrolyte abnormalities), is common in ICU patients and associated with worse outcomes. In general, most (absolute) adrenal insufficiency is secondary to abrupt withdrawal of therapeutic steroids. In the ICU, however, although total levels of cortisol may be normal, they may not respond appropriately to stress situations. Further, the typical diurnal variation of cortisol appreciated in normal volunteers is not seen in ICU patients, as stressors are not eliminated at night, making cortisol assay an easier task. In the past, relative adrenal insufficiency was defined by a cortisol level of less than 11 to 25 mcg/dL and/or failure to raise the level by more than 9 mcg/dL after stimulation by high-dose (250 mcg) ACTH.¹⁴⁹ However, there is much debate as to what cortisol level is appropriate in septic shock, what constitutes an adequate response to ACTH stimulation and what dose of ACTH should be used. After careful study, it appears that ACTH, or its synthetic analogue, cosyntropin, stimulation is not helpful in distinguishing those with relative adrenal insufficiency who would derive benefit from steroid administration. Prior work in the 1980 s and 90 s did not show benefit to high-dose steroid administration in septic shock. The more recent Annane French trial demonstrated a benefit to administration of low-dose steroid administration with concomitant mineralocorticoids in septic shock in terms of mortality.¹⁵⁰ However, the Corticosteroid Therapy of Septic Shock (CORTICUS) trial, a large multicenter study, did not demonstrate a mortality benefit to administration of steroids in septic shock.¹⁵¹ However, patients received therapy later than in the French trial and were not also administered mineralocorticoids. Subsequent meta-analyses of the role of steroids in septic shock reveal no difference in mortality but improved shock reversal.^{152,153} Current recommendations advise administration of low-dose, “replacement” steroids (glucocorticoids) to septic patients who remain hypotensive despite adequate volume resuscitation, particularly those whose serum cortisol levels are below 20 mcg/dL.²⁰ Still controversial is whether or not to administer a mineralocorticoid concomitantly to those felt adrenally insufficient. If fludrocortisone is not administered, then it is important to remember that glucocorticoids have varied mineralocorticoid potency – none seen with dexamethasone and half seen with methylprednisolone compared to hydrocortisone. Typically 200 to 300 mg hydrocortisone daily is administered in intermittent doses, every 8 hours, for 5 to 7 days and then tapered as guided by clinical response. A parallel to the relative insufficiency of cortisol seen in ICU patients with septic shock is that of arginine vasopressin. Therapy with low, replacement doses of vasopressin might be considered analogous to that with glucocorticoids and may, in fact, be complimentary to this therapy.¹⁵⁴ A final point to mention is that the induction agent etomidate is associated with relative adrenal insufficiency. Etomidate is laudatory because it is not associated with hemodynamic instability and, thus, had been favored in shock. However, etomidate is a reversible inhibitor of 11-beta-hydroxylase, and thus may cause transient adrenal insufficiency which theoretically can worsen outcome in sepsis. Studies have not definitively demonstrated worse outcome between patients intubated using etomidate versus other induction agents such as ketamine. Practitioners should balance the risks and benefits of etomidate administration and consider the transient administration of steroids to blunt adverse effects in the airway management of those with sepsis.¹⁵⁵

Thyroid Abnormalities

Thyroid abnormalities occur infrequently in ICU patients. Although the half-life of commonly administered thyroid medications is long, it is possible that chronically ill patients who eventually present to the ICU could develop severe hypothyroidism. The typical patient with myxedema coma has a long-standing need for replacement thyroid medications and is ill after infection or trauma. Patients

are hypothermic, bradycardic, and obtunded with low serum sodium and glucose levels. The treatment includes securing an airway, hydration, warming, and administration of thyroxine and hydrocortisone. The treatment of thyroid storm is discussed elsewhere in more detail. It occurs in patients with Graves disease or toxic nodular goiters who become infected, pregnant, traumatized, or undergo surgery. Supportive treatment includes ICU admission to monitor hemodynamic status and arrhythmias, cooling, hydration, and beta blockade. Propylthiouracil (PTU) or methimazole is administered both to inhibit the release of T4 and to block the conversion of T4 to T3. Thereafter, iodine as SSKI or Lugol solution is given, once hemodynamics have been stabilized to inhibit T4 release. Glucocorticoids may also be indicated. Finally, there is an entity of pseudohypothyroidism, the so-called sick syndrome, that occurs in ICU patients who have normal thyroid function but low levels of T3, freeT4, and T4 as T3 is converted to its isomer reverse T3. Several mechanisms can contribute to the inhibition of 5'-monodeiodination and therefore to the low serum T3 concentrations in patients with nonthyroidal illness. These include elevated cortisol levels with glucocorticoid therapy, free fatty acids that inhibit deiodinase, cytokines, and treatment with drugs that inhibit 5'-monodeiodinase activity such as amiodarone. No treatment is required. If there is additional evidence to suggest a diagnosis of hypothyroidism, critically ill patients, should receive cautious thyroid hormone replacement beginning with approximately half the expected full replacement dose of levothyroxine.

INFECTIOUS DISEASE ISSUES IN THE ICU

Sepsis Guidelines

Evidence-based sepsis resuscitation and global care guidelines are set forth in the Surviving Sepsis Campaign, now in its third version.²⁰ These guidelines prioritize care for those with the most acute forms of sepsis – that is, severe sepsis and septic shock. Severe sepsis refers to those infected patients with hypotension and/or hypoperfusion with organ dysfunction (manifested by oliguria, acute mental status change, new coagulopathy or thrombocytopenia, or acute lung injury). Septic shock refers to those who require administration of pressors despite initial volume resuscitation. Care of the septic patient with severe sepsis and septic shock is suggested to adhere to bundles that optimally should be completed within 3 and 6 hours ([Table 10-2](#)). Resuscitation targets a MAP of >65 mm Hg, a central venous pressure (CVP) of >8 mm Hg, and a central venous oxygen saturation (ScvO₂) of >70%. Pressors are administered if the initial fluid bolus does not achieve the targets above and inotropes and/or blood transfusion are given to maintain a hemoglobin >10 g/dL if the ScvO₂ goal is not met. The principal evidence underlying the resuscitation strategy is derived from Emanuel Rivers' early goal-directed therapy study (EGDT) published in 2001.¹⁵⁶ This single center trial allocated patients to usual care or CVP-directed intravenous fluid administration with MAP and ScvO₂ goals achieved by administration of dopamine, dobutamine, and packed red blood cells. In this study, Rivers and colleagues demonstrated a significant difference in mortality between the groups – 30.5% in the study patients versus 46.5% in the controls. Further, the current surviving sepsis guidelines render several specific recommendations regarding fluid administration. They advocate for the use of crystalloids as the initial fluid therapy of choice and against the use of hydroethyl starches and suggest that albumin may be beneficial if large volume crystalloid resuscitation is required.

12 In the interim, three trials have been conducted that call into question Rivers' resuscitation paradigm. The ProCESS trial, a large, multicenter controlled trial randomized patients into three groups with excellent protocol compliance (90%) and equivalent usage of early antibiotics. The three groups were the EGDT group (439 patients) exactly as described by Rivers with CVP and ScvO₂ monitoring and administration of dobutamine and packed cells. The second (protocol-based standard care) group (446 patients) was resuscitated to clinical euvolemia within 6 hours. Insertion of a CVC or and ScvO₂ catheter was not mandatory. Finally, a third (usual care) group (456 patients) was resuscitated according to the clinical judgment of the provider. Approximately half of the protocol and usual group patients received CVCs. Fluid administration was not clinically different between the protocol- and goal-directed therapy groups (2.3 L vs. 3.3 L, respectively). However, dobutamine use and packed cell transfusion was roughly eight times higher and double, respectively, in the EGDT group. Most importantly, there was no difference in 60-day, 90-day, or 1-year mortality, length of stay, or organ failure.³⁶ The second, the ARISE trial, randomized patients with early septic shock to receive EGDT (796 patients) or usual care (804 patients) and corroborated the results of the ProCESS trial. There was no difference in 90-day mortality, but the EGDT group was twice as likely to receive red blood cell transfusion and was six

times as likely to receive dobutamine.³⁷ The third trial – ProMISe from the United Kingdom, still awaits publication. It is apparent that these studies will result in a de-emphasis on CVP and ScvO₂-guided resuscitation in future iterations. Finally, the guidelines provide an in-depth evidence-based review of the components of global sepsis care, the evidence for which is described throughout this chapter.

Use of Procalcitonin to Guide Antibiotic Therapy

Procalcitonin, a precursor of calcitonin with a half-life of about 24 hours, is released in response to bacterial toxins and interleukin-1b and has been identified as a marker of sepsis and bacterial infection for nearly a decade. Procalcitonin increases within 4 to 6 hours of bacterial infection, is attenuated in the presence of viral infection and not affected in the presence of fungal infections. Far more important clinically is the observation that procalcitonin levels halve once bacterial infection is controlled by antibacterials. Protocols have been developed to stop empiric or therapeutic antibiotics once procalcitonin levels decrease by 80% or to an absolute level of 0 to 0.5 ng/mL. Seven randomized trials in ICU patients were subjected to a systematic review and meta-analysis suggesting that procalcitonin assay reduces antibiotic use by an average of two days per patient without otherwise affecting outcome.¹⁵⁷ An in-depth economic analysis suggests that use of procalcitonin is effective in the ICU setting.¹⁵⁸ More recent studies support the notion that use of procalcitonin is useful in determining when to stop antibiotics in ICU patients and that these shorter therapeutic courses are not associated with a difference in outcome.^{159,160}

Central Line Associated Blood Stream Infections

Central line associated blood stream infections (CLABSI) can be an important cause of morbidity, resource utilization, and even attributable mortality in ICU patients. Infection control measures have been successful in dramatically lowering the incidence of this infection, defined as 15 colony forming units (cfu)/mL by semiquantitative or 10³ by quantitative means. Perhaps the most successful intervention to preventing CLABSI is to remove (or not insert) central catheters if they are not needed; this is the cornerstone of care bundles or checklists (Table 10-3).¹⁶¹ Antiseptic or antibiotic-coated catheters should be considered in ICUs with a high baseline rate of infection after employing less costly measures. Chlorhexidine-impregnated dressings lower CLABSI rates as well.¹⁶² Routine wire changing of catheters does not decrease CLABSI rate. In the past the subclavian site was felt to be the least prone to infection; however, recent studies indicate that internal jugular (and perhaps even femoral) catheters are not much worse. Further, no randomized controlled trial compares subclavian versus internal jugular versus femoral insertion in a single study.

Catheter Associated Urinary Tract Infections

Infection control measures have also been undertaken to prevent catheter associated urinary tract infections (CAUTI), a common cause of morbidity, but rarely of mortality, in surgical ICU patients. CAUTI are the leading cause of secondary healthcare-associated bacteremia and may be associated with symptomatic or asymptomatic bacteriuria of >10 cfu/mL.⁵ Most strategies focus on prompt removal of indwelling catheters. There may be some role for use of antiseptic- (silver preparations) or antibiotic-coated catheters (minocycline-rifampin) in high-risk patients, although clinical trials have not been definitive.^{164,165}

The Use of Selective Oral and Selective Digestive Decontamination (SOD and SDD) and Other Strategies to Address Resistant Organisms in the ICU

Antibiotic-resistant bacteria are discussed more in detail in this text. Those relevant to ICU patients include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococcus, and multi-drug resistant gram negative pathogens, including carbapenem-resistant enterobacteriaceae. Various infection control strategies have been promulgated in ICU patients to address these virulent organisms. We will discuss the use of selective decontamination and MRSA decontamination strategies here. The practice of selective decontamination was developed many decades ago and is used extensively in surgical and trauma patients in Europe. Its goal is to minimize ventilator-associated pneumonia to lessen multiple organ dysfunction and improve outcome in high-risk populations. The cornerstone of the therapy is the administration of a short course (4 day) of parenteral antibiotics to address respiratory gram negative pathogens, typically a second generation cephalosporin. SOD strategies add use of a chlorhexidine mouthwash. SDD employs a nonabsorbable enteral antibiotic (such

as colistin) instead. Although there is a more robust experience with selective digestive rather than oral decontamination, both strategies are associated with a reduction in ventilator-associated pneumonia without a concomitant change in mortality.¹⁶⁵ Another systematic review demonstrated a reduction in multiorgan failure rates, but not of mortality.¹⁶⁶ A large crossover cluster trial of nearly 6,000 ICU patients in Denmark demonstrated that SOD and SDD both decreased mortality by roughly 15%, although SOD was markedly less expensive. For whatever reason, perhaps the concern for antibiotic resistance, the practice of decontamination by either route has not garnered interest in the United States. The Danish group has noted, however, that antibiotic resistance was actually lower after institution of decontamination.¹⁶⁷ However, another large Danish trial demonstrated that SDD patients did experience higher rates of aminoglycoside resistance by gram negative organisms.¹⁶⁸ Specific strategies to provide MRSA decontamination are focused on certain principles: that MRSA colonization can be rapidly identified by aggressive screening protocols using polymerase chain reaction (PCR) technology, that MRSA colonization ultimately leads to bacteremia and that therapies exist to successfully decolonize patients. The clinical data are confusing and various society guidelines have reached different conclusions regarding universal screening. Nonetheless, in the United States, 35% or more of all precaution days are due to MRSA and screening increases these contact days by 15%. A large Veterans Affairs initiative involving both ward and ICU patients demonstrated that MRSA screening decreased infection rates.¹⁶⁹ Two other large studies, one of surgical patients¹⁷⁰ and another of mixed ICU patients¹⁷¹ did not show benefit of MRSA screening in lowering infection rate. Several studies have investigated the role of MRSA-directed decontamination, using such agents as topical chlorhexidine on washcloths and intranasal mupirocin with or without oral rifampin and doxycycline. This strategy has been successful in liver transplant patients¹⁷² and in mixed ICU patients¹⁷³ in terms of decreasing colonization, infection, and bacteremia. A multicenter US study randomized ICUs to MRSA screening and isolation, targeted decolonization, or universal decolonization with topical chlorhexidine and nasal mupirocin. Interestingly, the latter strategy was associated with reduced MRSA colonization and all-cause infections (but not MRSA), suggesting that chlorhexidine is the most efficacious component of the strategy.¹⁷³ Chlorhexidine can also decrease colonization, and perhaps infection, with VRE, but its effect of gram negative organisms is less certain.¹⁷⁴

Chapter 11

Fluids, Electrolytes, and Acid–Base Balance

Richard B. Wait, M. George DeBusk, and Jeffry Nahmias

Key Points

- 1 The human body is conceptualized as being composed of two primary fluid compartments: extracellular fluid (ECF) and intracellular fluid (ICF). The two compartments are separated by cellular membranes.
 - 2 The ECF can be further divided into smaller compartments: transcellular fluid, plasma, interstitial fluid, and bone/connective tissue fluid. Blood is a composite compartment containing both ECF (plasma) and ICF (red cell volume).
 - 3 Sodium and potassium are the dominant cations of the ECF and ICF, respectively.
 - 4 Extracellular tonicity is under tight regulation by osmoreceptors found in the hypothalamus. As sodium accounts for the majority of ECF tonicity, these receptors function essentially as ECF monitors.
 - 5 Effective circulating volume is sensed by volume receptors (capacitance vessels, atria, hepatic, and central nervous system [CNS]) and pressure receptors (aortic arch, carotid, and intrarenal) that alter sodium and water balance mediated by renin–angiotensin, aldosterone, atrial natriuretic peptide (ANP), dopamine, and renal prostaglandins.
 - 6 Water losses are composed of both sensible (i.e., measurable) losses via urine, stool, and sweat and insensible (i.e., immeasurable) via evaporative loss from the skin, respiratory tract, or open abdomen.
 - 7 Goals of fluid therapy are to normalize body fluid compartment volumes and electrolyte concentrations. This can be achieved with crystalloid (preferable) or colloid infusion to correct deficits and/or match ongoing and expected losses.
 - 8 The major electrolytes (Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , and HPO_4^{2-}) should be monitored and replaced, when possible, with respect to the pathophysiology of various disease states.
 - 9 Acid–base balance is carefully buffered within very narrow limits. Acid–base disturbances are frequently mixed, involving combined respiratory and metabolic derangements.
-

In this chapter, the normal physiologic mechanisms of fluid and electrolyte homeostasis, inclusive of acid–base physiology, are reviewed. This will be the starting point for a discussion of fluid and electrolyte pathophysiology and the management of specific clinical situations. With a thorough understanding of disease- and injury-related alterations from normal fluid volume and electrolyte physiology, one can effectively care for all surgical and critically ill patients.

BODY FLUIDS

Total Body Water and Body Fluid Compartments

Total body water (TBW) is defined as the total amount of water contained within the body. The relationship between TBW and body weight varies according to the percentage of body fat.¹ The average TBW in adult men is 60% of total body weight and 55% in adult women. In infants, water makes up approximately 75% to 80% of body weight. This figure decreases to approximately 65% by 1 year of age and continues to decrease slowly throughout life, primarily related to decreases in lean body mass. Estimates of TBW can be empirically adjusted for the obese and thin body habitus. In obesity, estimates of TBW can be decreased by 10% to 20%. In very thin individuals, estimates can be increased by up to 10%.¹

- 1 TBW is principally distributed into the intracellular and extracellular compartments which are in

dynamic equilibrium (Table 11-1). ICF makes up approximately two-thirds of the TBW, and the remaining one-third is composed of ECF. Using these techniques, ECF volume estimates range from 30% to 33% of TBW, or approximately 20% of body weight.²

2 The ECF compartment is subdivided into the interstitial and intravascular spaces. The interstitial space extends from the blood vessels to the cells. It includes the complex ground substance making up the acellular tissue matrix. The water in this space exists in free and bound phases. The free phase contains water that is freely exchangeable with intravascular, lymphatic, and intracellular water. It is in a constant state of flux. The bound phase is much less freely exchangeable. It is composed of water that hydrates matrix materials such as glycosaminoglycans and mucopolysaccharides. Interstitial water volume can be calculated as ECF–intravascular space volume and constitutes approximately 25% of TBW, or 15% of body weight. The intravascular space accounts for 25% of the ECF and contains the plasma volume, which is approximately 8% of the TBW or 5% of body weight.

The transcellular space, a third and smaller component of ECF, consists of water that is separated from other compartments by endothelial and epithelial barriers, including cerebrospinal, ocular, and synovial fluids, as well as fluid in the gastrointestinal (GI) tract. Under normal circumstances, fluid in the transcellular space is not easily exchangeable with that in other compartments.³

Composition of Body Fluids

3 Sodium and potassium are the dominant cations in the body. As mentioned above, sodium is restricted primarily to the ECF. Sodium content in an average adult is approximately 60 mEq/kg. Approximately 25% is confined to bone and is nonexchangeable. Of the exchangeable fraction, approximately 85% is in the ECF. Potassium, calcium, and magnesium make up the remainder, smaller fraction, of the cations present in the ECF (Table 11-2).

Table 11-1 Body Fluid Compartments

	Body Weight (%)	Total Body Water (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33
Intravascular	5	8
Interstitial	15	25
Transcellular	2	4

In the ICF, potassium is the dominant cation. Total body potassium is normally approximately 42 mEq/kg, and most of this potassium is intracellular and freely exchangeable. Magnesium and sodium ions also contribute to a lesser extent to the cationic component of the ICF. Phosphate, sulfate anions, bicarbonate, and intracellular proteins balance these cations.

The Gibbs–Donnan equilibrium describes the relationship between charged particles in a solution that are unevenly distributed across a semipermeable membrane.⁴ This special type of equilibrium exists between the ICF and ECF because of the high concentration of protein and nondiffusible phosphates in the cell. ECF cations are in electrochemical balance with chloride, bicarbonate, phosphate, and sulfate anions, although chloride is the major contributor to this balance. In addition, anionic proteins contribute to ion balance in plasma but not in interstitial fluid, which is essentially an ultrafiltrate of plasma that normally contains little protein. As a result, the content of both cations and anions in interstitial fluid is slightly higher than in plasma (Table 11-2).

Interstitial fluid, in comparison, contains little protein. These impermeable intracellular negative charges tend to favor diffusion of permeable anions into the ECF. The Gibbs–Donnan equilibrium also exists across the capillary endothelial membrane because the concentration of protein is higher on the blood side of the capillary than on the interstitial fluid side. Thus, the concentrations of diffusible ions are not necessarily equal across these membranes because of the presence of these complex anions.

Table 11-2 Electrolyte Concentrations of Intracellular and Extracellular Fluid Compartments

	Extracellular Fluid (mEq/L)		
	Plasma	Interstitial	Intracellular Fluid (mEq/L)
Cations			
Na ⁺	140	146	12
K ⁺	4	4	150
Ca ²⁺	5	3	10 ⁻⁷
Mg ²⁺	2	1	7
Anions			
Cl ⁻	103	114	3
HCO ₃ ⁻	24	27	10
SO ₄ ²⁻	1	1	—
HPO ₄ ³⁻	2	2	116
Protein	16	5	40
Organic anions	5	5	—

Osmotic Activity of Body Fluids

The concentration of solutes in the fluid compartments depends on the osmotic activity generated by the ion species contained in each compartment. When two solutions are separated by a semipermeable membrane, water moves across the membrane to equalize the concentration of osmotically active particles to which the membrane is impermeable. The maintenance of osmotic equilibrium across a semipermeable membrane is based primarily on the number of solute particles rather than on the molar concentration of the solution on each side of the membrane due to the flow of water.

The unit of measurement of osmotically active particles is the osmole (Osm) or milliosmole (mOsm) rather than the conventional units of solute concentration such as milliequivalents per liter (mEq/L). In solution, osmolarity (mOsm/L) and osmolality (mOsm/kg water) define the osmotic activity of particles. When 1 mol of NaCl dissociates in water to Na⁺ and Cl⁻, it produces 2 Osm. The same relationship holds true of dissociating salts of multivalent ions such as calcium and magnesium. One mol of a nondissociating molecule, such as glucose, produces 1 Osm (1,000 mOsm). The measured osmolality of a solution may not equal the calculated osmolality if the ions do not totally dissociate.

Body fluids are aqueous solutions composed of water and various solutes within the different body fluid compartments. Because cells are bounded by a semipermeable membrane, adding free water to the fluid surrounding a cell causes water to move across the cell membrane to equalize the osmolality differential between the intracellular and extracellular compartments. On a larger scale, adding free water to the ECF of the body causes an immediate expansion of the extracellular space, followed by a redistribution of water into the intracellular compartment (Fig. 11-1A). Conversely, loss of free water from the extracellular space ultimately leads to a shift of water from the intracellular to the extracellular space (Fig. 11-1B). An osmotic gradient of just 1 mOsm generates a pressure gradient of 19.3 mm Hg.

Colloid Oncotic Pressure (Colloid Osmotic Pressure)

Plasma proteins are confined primarily to the intravascular space and contribute to the osmotic pressure developed between the plasma and the interstitial fluid. Normal plasma protein levels of 7 g/dL contribute approximately 0.8 mOsm/L.

Figure 11-1. A: The equilibration of water from the extracellular to the intracellular space after the addition of free water to the

extracellular fluid compartment. Osmolality transiently decreases in the extracellular compartment, causing water to move across the cell membranes into the intracellular space. **B:** Similar shifts after free water loss from the extracellular compartment. Water moves from the intracellular space to the extracellular space in response to the osmolal gradient that is established.

Osmoregulation

4 Osmolality of body fluids stays fairly constant at approximately 285 to 295 mOsm/L as the result of tightly regulated water balance. Osmoreceptor cells in the paraventricular and supraoptic nuclei of the hypothalamus exert central control over the thirst mechanism and antidiuretic hormone (ADH) secretion from the posterior pituitary.⁵ In the presence of excess free water, ECF osmolality falls toward 280 mOsm/kg H₂O, thirst is inhibited, and ADH levels decline. In the absence of ADH, the permeability of renal collecting tubules to water is decreased, causing free water reabsorption to decrease and excretion to increase. Urine osmolality (U_{osm}) can decline to 50 mOsm/kg H₂O (Fig. 11-2). As excess free water is eliminated, P_{osm} begins to rise. Conversely, free water depletion causes an increase in P_{osm} . As P_{osm} approaches 295 mOsm/kg H₂O, thirst is stimulated as is ADH secretion. As ADH levels rise to approximately 5 pg/mL, the renal collecting tubules become maximally permeable to water. Water is reabsorbed from the collecting ducts in response to the concentration gradient developed in the renal medullary interstitium. Thus, the final concentration of urine depends on both the permeability of the collecting ducts (controlled by ADH secretion) and the concentration of the medullary interstitium.⁵ Maximal U_{osm} may approach 1,200 mOsm/kg H₂O. The net effect of these mechanisms is to promptly return high or low P_{osm} to normal. The high sensitivity of the osmoreceptors and the responsiveness of the ADH feedback system ensure that even small changes in P_{osm} result in marked alterations in urine concentration. This relation can be expressed as follows:

$$\text{Urine osmolality} = 95 \times \text{Plasma osmolality}$$

Thus, a 1-mOsm change in P_{osm} results in a 95-fold change in U_{osm} .

Angiotensin II and neural input from medullary baroreceptors can also influence ADH secretion and thirst, thus tying water balance to hemodynamic alterations. Relatively small changes in pressure have little effect on ADH secretion, but large decreases in pressure can cause tremendous increases in ADH release. Therefore, ADH release as a response to changes in serum osmolality is regulated by a very sensitive system (only small changes in serum osmolality outside its normal range lead to dramatic changes in ADH release), while the nonosmotic release of ADH occurs in the setting of profound hypotension for the purposes of preserving volume homeostasis with the subsequent effect of water retention regardless of serum osmolality (Fig. 11-3).

Tonicity of Body Fluids

Tonicity refers to the effect of the particles on cell volume. (NB: *Osmolality* defines the concentration of osmotically active particles in solution.) Permeable solutes can freely cross cell membranes, whereas impermeable solutes cannot. Although permeable solutes contribute to the osmolality of a solution, they have no effect on tonicity because they contribute neither to oncotic gradients across cell membranes nor to alterations in cell volume. Sodium is an example of an impermeable solute that affects both osmolality and tonicity. Urea and ethanol are permeable solutes that contribute to osmolality but have little effect on tonicity because they distribute equally across membranes.

Figure 11-2. The relation of plasma antidiuretic hormone (arginine vasopressin [AVP]) secretion to plasma (A) and urine (B) osmolality in healthy adults in varying states of water balance. (Reproduced with permission from Robertson GL, Berl T. Water metabolism. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:392.)

Figure 11-3. Effect of acute changes in blood volume or pressure on the osmoregulation of antidiuretic hormone (ADH; vasopressin). The heavy oblique line in the center represents the relation between plasma ADH and osmolality under normovolemic, normotensive conditions. The lines to the left and right show the shift in the relation when blood volume or blood pressure is acutely decreased or increased by the percentage indicated in the circles. (Reproduced with permission from Robertson GL. Physiology of ADH secretion. *Kidney Int* 1987;32(Suppl 21):520.)

Both impermeable and permeable solutes can contribute to *hyperosmolar* and *hypoosmolar* states. However, hypoosmolar states are always accompanied by hypotonicity, whereas hyperosmolar states are not always associated with hypertonicity. There may be marked hyperosmolality without hypertonicity with elevation of blood urea nitrogen (BUN) levels because urea is a freely permeable molecule. In contrast, elevated levels of plasma glucose in diabetic patients are associated with hyperosmolality and associated hypertonicity. Insulin increases the transport of glucose across cell membranes, rendering these osmoles *ineffective* and reducing hypertonicity. Plasma hyperglycemia is associated with the movement of intracellular water to the extracellular space. This causes expansion of ECF and plasma volume and a consequent decrease in the concentration of plasma sodium. For every 100 mg/dL elevation in blood glucose, measured serum sodium is calculated to fall 1.5 mEq/L, without an actual alteration of body sodium content. The osmotic diuresis caused by the elevated glucose level tends to normalize the serum sodium if adequate hydration is maintained. Some patients with uncontrolled diabetes also have marked hyperlipidemia. Because of this, the concentration of measured sodium falls. This condition is termed *pseudohyponatremia*, an artifactual hyponatremia most commonly caused by severe hypertriglyceridemia, or by severe hyperproteinemia.

Plasma osmolality (P_{osm}) is an excellent measure of total body osmolality. Osmolality differentials between fluid compartments are only transient because fluid shifts maintain isosmotic conditions. Sodium is the predominant extracellular cation; thus, estimates of P_{osm} can be made by simply doubling the serum sodium concentration (serum $[\text{Na}^+]$):

$$P_{\text{osm}} (\text{mOsm/L}) = 2 \times \text{serum } [\text{Na}^+]$$

Because glucose and BUN may make significant contributions to P_{osm} in certain disease states, this formula is modified for glucose and for BUN:

$$P_{\text{osm}} (\text{mOsm/L}) = 2 \times \text{Serum } [\text{Na}^+] - \text{Glucose}/18 - \text{BUN}/2.8$$

Discrepancies of greater than 15 mOsm/L between calculated P_{osm} and P_{osm} measured in the clinical laboratory may be the result of the presence of other osmotically active particles, such as mannitol, ethanol, or ethylene glycol, or of a reduced fraction of plasma water secondary to high levels of myeloma proteins or hypertriglyceridemia.

FLUID BALANCE

Sodium Concentration and Water Balance

Abnormalities in serum sodium are usually indicative of abnormal TBW content. This is due to sodium being the primary extracellular cation. As potassium is the predominant intracellular cation, the serum $[\text{Na}^+]$ approximates the sum of the exchangeable total body sodium (Na^+_{e}) and total body

exchangeable potassium (K^+_e) divided by TBW:

$$\text{Serum } [Na^+] = (Na^+_e - K^+_e)/TBW$$

Because the sum of total body solute content ($Na^+_e - K^+_e$) remains relatively stable over time, changes in TBW content is, therefore, inversely proportional to changes in the serum $[Na^+]$ (Fig. 11-4).

Volume Control

5 Changes in volume (i.e., hypovolemic/nonosmotic stimuli) are detected by both osmoreceptors and baroreceptors.³ The osmoreceptors are responsible for the day-to-day fine-tuning of volume by responding to changes in tonicity, whereas the baroreceptors contribute relatively little to the control of fluid balance under normal conditions. As mentioned previously, large changes in circulating volume (10% to 20% blood volume loss) can modify the osmoregulation of ADH secretion. Cardiac atrial baroreceptors control volume by means of sympathetic and parasympathetic neural mechanisms, whereas ANP released by atrial myocytes in response to atrial wall distention may influence sodium-linked volume control by inhibition of renal sodium reabsorption.⁶⁻⁸

Figure 11-4. Relation between serum $[Na^+]$ and the ratio of $(Na^+_e + K^+_e)$ to total body water (TBW). (Reproduced with permission from Edelman IS, Liebman J, O'Meara MP, et al. Interrelationships between serum sodium concentration, serum osmolarity and total exchangeable sodium, total exchangeable potassium and total body water. *J Clin Invest* 1958;37:1236.)

Osmoreceptors

Specialized cells in the hypothalamus that respond to changes in extracellular tonicity are known as *osmoreceptors*. It is believed that the activity of ion channels in the cell membrane, aquaporins, and changes in cell volume contribute to the function of these receptors. As the majority of the ECF tonicity is contributed by sodium, under normal physiologic conditions, these receptors function as “osmo-sodium” receptors. Osmoreceptors can respond to changes in tonicity as small as a few percent. In effect, these receptors monitor water balance by monitoring the tonic effect of changes in water volume. Therefore, ECF $[Na^+]$ is an effective monitor of TBW.

Baroreceptor Modulation of Volume Control

Effective circulating volume describes that portion of the extracellular volume that perfuses the organs of the body and affects the baroreceptors. The effective circulating volume normally corresponds to the intravascular volume.

Changes in the effective circulating volume are sensed by volume receptors in the intrathoracic capacitance vessels and atria, pressure receptors of the aortic arch and carotid arteries, intrarenal baroreceptors, and hepatic and cerebrospinal volume receptors.^{8,9} These stretch receptors respond to changes in pressure and circulating volume and, through a complex system of neural and hormonal actions, alter sodium and water balance in the kidneys. Hormonal effects are mediated by the renin-angiotensin system, aldosterone, ANP, dopamine, and renal prostaglandins.

Baroreceptor Function

The low-pressure baroreceptors of the intrathoracic vena cava and atria are located in vessels that are distensible and not affected by sympathetic stimulation; thus, they are ideally situated to detect changes in venous volume.⁸ These receptors send continuous signals through vagal afferent nerves to the cardiovascular control centers of the medulla and hypothalamus, which, in turn, send signals through parasympathetic and sympathetic fibers to the heart and kidneys. Changes in stretch of these vessels

result in changes in the frequency of signal output from these receptors. Increases in atrial distention cause decreased nerve signal traffic, which ultimately causes increased sympathetic tone to the heart, which results in tachycardia and inhibition of sympathetic tone to the kidney. This leads to increased renal blood flow and decreased tubular sodium reabsorption. Conversely, low volume in the intrathoracic vessels results in increased sympathetic tone to the kidneys, decreased renal blood flow, and increased sodium reabsorption.

The effects of sympathetic activity on renal sodium reabsorption are probably mediated both by direct tubular innervation and by β -adrenergic stimulation of renin production. Whether this effect is crucial to fine regulation of sodium balance under normal physiologic conditions is unclear. Renal denervation in conscious, unstressed animals results in minimal alteration of either blood flow or sodium reabsorption. The effects of renal denervation become much more marked with anesthesia administration or hypotension, suggesting that sympathetic effects on renal function may be important during periods of physiologic stress.

Arterial baroreceptors are located in the aortic arch and carotid arteries. They respond to changes in heart rate, arterial pressure, and the rate of rise in the arterial pressure. Arterial baroreceptors are important during periods in which there are extremes in the changes in arterial pressure characteristics, as occur during hemorrhage. They are probably not involved in controlling subtle volume or pressure changes. In addition to large-vessel baroreceptors, there are arterial baroreceptors in the afferent arterioles of the kidneys. These baroreceptors modulate renin secretion. Increases in transmural pressure cause suppression of renin release, and decreases in transmural pressure stimulate renin release.

Hormonal Mediators of Volume Control

Renin–Angiotensin System. Renin is a proteolytic enzyme that is released from the juxtaglomerular cells of afferent arterioles in the kidney in response to several stimuli. These include changes in arterial pressure, changes in sodium chloride delivery to the macula densa of the distal convoluted tubule, increases in β -adrenergic activity, and increases in cellular cyclic adenosine monophosphate.

Renin cleaves angiotensin I from circulating angiotensinogen, produced by the liver. Angiotensin I is cleaved to the octapeptide angiotensin II by angiotensin-converting enzyme (ACE), which is produced by vascular endothelial cells. One pass through the pulmonary microvasculature converts most angiotensin I to angiotensin II. Angiotensin II acts both locally and systemically to increase vascular tone. It also stimulates catecholamine release from the adrenal medulla, increases sympathetic tone through central effects, and stimulates catecholamine release from sympathetic nerve terminals. Angiotensin II affects sodium reabsorption by decreasing renal blood flow and glomerular filtration. This results in altered tubuloglomerular feedback, the mechanism by which changes in distal tubular NaCl delivery alter glomerular blood flow. Finally, angiotensin II increases sodium reabsorption by direct tubular action as well as by stimulation of aldosterone release from the adrenal cortex. The multiplicity of actions of angiotensin is depicted in [Figure 11-5](#).

Aldosterone. Aldosterone is a mineralocorticoid produced in the *zona glomerulosa* of the adrenal cortex. Aldosterone increases renal tubular reabsorption of sodium. Aldosterone acts directly on the distal tubule cells by modifying gene expression and stabilizing the epithelial Na⁺ channel in the open state and by increasing the number of channels in the apical membrane of these cells.⁵ By increasing protein production in these tubular cells, aldosterone induces an influx of sodium, which causes an increase in cellular Na⁺-K⁺-adenosine triphosphatase activity. The net result is increased sodium reabsorption and the obligate loss of potassium via the renal outer medullary potassium (ROMK) channel. Although the primary regulator of aldosterone secretion is angiotensin II, aldosterone release is also stimulated by increased potassium levels, adrenocorticotrophic hormone, endothelins, and prostaglandins.¹⁰

Figure 11-5. Multiple effects of increased angiotensin II release in response to the stimulus of decreased extracellular volume.

Atrial and Renal Natriuretic Peptides. ANP is synthesized and released by atrial myocytes in response to atrial wall distention. As mentioned previously, small changes in right atrial pressure produce large increases in plasma levels of ANP.^{7,8} There is evidence that ANP has a direct inhibitory effect on renal sodium reabsorption, which is probably maximal at the level of the medullary collecting tubules. Although pharmacologic doses of ANP can cause changes in both renal blood flow and glomerular filtration rate (GFR), physiologic levels do not appear to have any major effect on these parameters. Other active fragments of the ANP prohormone have been found to have natriuretic activity. The best described is urodilatin, also known as *renal natriuretic* peptide. Urodilatin is a peptide with ANP-like activity that was first isolated from human urine. It is synthesized and lumenally secreted by cortical collecting tubule cells. Like ANP, it is released in the kidney tubules in response to atrial distention and saline loading. It is at least twice as potent as ANP, acting in the distal nephron to cause a rise in intracellular cyclic guanosine monophosphate, leading to sodium, chloride, and water diuresis. ANP and other peptides may play an important role in controlling intravascular volume and water and electrolyte secretion.

Renal Prostaglandins. Renal prostaglandins appear to play a role in volume control, although under normal physiologic conditions, this role may be minimal. Disease states such as sepsis and jaundice, or the induction of anesthesia, may make the contribution of the prostaglandins more pronounced.⁹

Prostaglandin E₂ (PGE₂) and prostaglandin I₂ (PGI₂) appear to be the predominant prostaglandins produced in the kidney. PGE₂ is produced primarily by the interstitial cells of the renal medulla. The release of PGE₂ has been shown to depend on increases in interstitial pressure, which can be induced by changes in renal perfusion, ureteral obstruction, or alterations in oncotic pressure. Under these conditions, PGE₂ increases sodium excretion in the absence of changes in GFR. PGE₂ antagonizes the action of vasopressin (ADH) and inhibits ADH-induced sodium reabsorption along the medullary collecting duct and thick ascending limb. PGI₂ is produced by the glomeruli and endothelial cells of the kidney and is present in the greatest concentrations in the renal cortex. PGI₂ is a vasodilator, and its effects on renal vascular resistance increase both renal blood flow and GFR. PGI₂ production is augmented by increases in angiotensin, catecholamines, and sympathetic tone and may act to counterbalance their vasoconstricting effects. Although under normal physiologic conditions inhibition of prostaglandin production has little effect on renal function, administration of nonsteroidal anti-inflammatory agents, which inhibit cyclooxygenase, to patients with conditions known to cause renal dysfunction (e.g., cirrhosis) can precipitate renal failure, presumably because of loss of the protective effects of the renal prostaglandins.

Endothelins. Endothelins are peptide vasoconstrictors that are involved in volume and pressure regulation.¹⁰ Endothelin is produced and released by endothelial and other cells to act on adjacent smooth muscle cells. In addition to increasing peripheral resistance, endothelin infusion has a direct inotropic effect on the myocardium. In contrast to its vasoconstrictive effects, endothelin stimulates the release of other vasoactive mediators, particularly endogenous vasodilators like nitric oxide, which act to limit its intense vasoconstrictor effect.

Endothelin exerts a complex influence on sodium and water exchange through varied interactions with many other hormones that govern fluid and electrolyte balance. One net effect of endothelin is a decrease in the filtered load of sodium in the kidney. This results in inhibition of water reabsorption and

decreased sodium excretion. Endothelin increases ANP secretion, activates ACE, and inhibits renin release by the juxtaglomerular apparatus. At low doses, endothelin-1 produces natriuresis and diuresis. Endothelin also modulates the biosynthesis of aldosterone, thereby inhibiting water reabsorption through aldosterone-controlled mechanisms. Vasopressin-mediated water reabsorption is also inhibited. Endothelin appears to have complex interactions with other regulators of renal perfusion and handling of water and electrolytes, which has stimulated research to evaluate the contribution of endothelin to the pathophysiology of various renal diseases.¹¹

Nitric Oxide. Nitric oxide is a short-lived free radical produced from l-arginine by nitric oxide synthases.¹¹ This substance has numerous biologic functions, including regulation of vascular tone and tissue blood flow. Nitric oxide is produced in renal smooth muscle cells, mesangial cells, tubules, and endothelial cells and participates in the regulation of renal hemodynamics and renal handling of water and electrolytes. Nitric oxide and PGI₂ each independently cause renal vasodilation in response to a variety of stimuli. Nitric oxide contributes to tubuloglomerular feedback, which modulates the delivery and reabsorption of sodium and chloride in the renal tubules. Nitric oxide also regulates renin release by the juxtaglomerular apparatus. Nitric oxide produced in the proximal tubule may mediate the effects of angiotensin on tubular reabsorption.¹¹

Normal Water and Electrolyte Exchange

Surgical patients are prone to fluid and electrolyte abnormalities. It is important to recognize that disease states, trauma, and stress-related abnormalities – especially those caused by a surgical procedure – alter many of the body’s fundamental homeostatic mechanisms. It is therefore important to understand normal fluid and electrolyte balance to avoid additional iatrogenic perturbations of these mechanisms.

Normal Water Exchange

6 Water losses are both sensible (measurable) and insensible (unmeasurable). Measurable losses include urinary and intestinal. Table 11-3 summarizes the normal sensible and insensible losses encountered in a 24-hour period. The volumes of these losses may vary considerably especially in disease states. Under normal conditions, the minimal amount of water needed to excrete normal metabolic waste products is approximately 300 to 500 mL/day.

The GI tract has a net secretory action down to the level of the jejunum. After that, the resorptive capacity of the remainder of the small and large bowel acts to keep further water loss to a minimum. Fecal water loss is usually trivial: ~150 mL/day. In disease conditions like bowel obstruction, severe diarrhea, and enterocutaneous fistulas, GI losses of water and electrolytes can be significant causing secondary pathophysiologic conditions.

Table 11-3 Body Fluid Compartments

	Average Daily Volume (mL)	Minimal Daily Volume (mL)
Sensible losses		
Urinary	800–1,500	300
Intestinal	0–250	0
Sweat	0	0
Insensible losses		
Lungs and skin	600–900	600–900

Adapted from Shires GT, Canizaro PC. Fluid and electrolyte management of the surgical patient. In: Sabiston DC, ed. *Textbook of Surgery*. Philadelphia, PA: WB Saunders; 1986:77, with permission.

Sweating and diaphoresis are active processes involving the secretion of a hypotonic mixture of electrolytes and water. Sweating functions to allow the convective dissipation of heat. Diaphoresis is a similar effect, but is a pathophysiologic state stemming from a disease process.

These aforementioned conditions are distinct from the immeasurable, evaporative loss of water from the skin under normal conditions (Table 11-3). Evaporative skin losses are increased with an increase in body surface area (especially infants and small children), patient temperature, and the relative humidity of the environment. Evaporation through the skin functions through convective heat loss and is proportional to calories expended. Approximately 30 mL of water is lost for every 100 kcal expended. Respiratory exchange depends on ambient temperature, relative humidity, and on the amount of air

flow. Overall, normal insensible water losses average approximately 8 to 12 mL/kg/day. Insensible water loss increases 10% for each degree of body temperature above 37.2°C (99°F). In addition, patients who breathe unhumidified air lose additional free water. Conversely, patients who are on respirators or who breathe air that is 100% humidified have no respiratory losses and may gain free water.

FLUID AND ELECTROLYTE THERAPY

Parenteral Solutions

Crystalloids

7 The most widely used parenteral solutions are composed most commonly of sodium and chloride. They are collectively referred to as *crystalloids* (based on the solid, room temperature form of the primary ingredient sodium chloride). Crystalloids are inexpensive and highly effective for fluid maintenance and rapid volume replacement. They also have excellent safety profiles. Although crystalloid-induced hypercoagulability has been reported, its causes are multifactorial and poorly understood.^{12–15} Clinically, this does not represent a significant problem.

The most commonly used crystalloid solutions available for parenteral administration are found in Table 11-4. Selection of the appropriate fluid requires assessment of the patient’s maintenance fluid needs, existing fluid deficits and anticipated ongoing fluid losses. When a single solution does not accurately replace the required electrolyte components, bolus administration of specific replacement solutions is commonly performed. It is commonplace to use more than one type of crystalloid solution. This is commonly seen with parenteral medication formulations that may have specific carrier-fluid requirements. Ions such as potassium, magnesium, or calcium may be necessary and can be added to parenteral solutions to suit the patient’s requirements.

Table 11-4 Electrolyte Content of Commonly Used Intravenous Crystalloid Solutions

Solution	Electrolyte (mEq/L)					
	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	Cl ⁻	...
0.9% NaCl	154	—	—	—	154	—
0.45% NaCl	77	—	—	—	77	—
0.33% NaCl	56	—	—	—	56	—
0.2% NaCl	34	—	—	—	34	—
Lactated Ringer	130	4	4	—	109	28
3.0% NaCl	513	—	—	—	513	—
5.0% NaCl	855	—	—	—	855	—

Isotonic saline (0.9% sodium chloride or *normal saline*) contains 154 mEq of both sodium and chloride. Although this solution can be useful in patients with hyponatremia or hypochloremia, the excess of both sodium and chloride can lead to acid–base disturbances. For example, infusion of large volumes of 0.9% saline can lead to a hyperchloremic metabolic acidosis. In addition, the pH of normal saline and of the related solutions (0.45%, 0.33%, and 0.2% saline) is 4.0 to 5.0 further decreasing the blood pH.

Lactated Ringer solution is a buffered solution composed of the conjugate-base lactate. It was created in the 1930s by an American pediatrician, Alexis Hartmann, as a treatment for metabolic acidosis. The solution has a lower sodium and chloride content (130 mEq/L) and adds a very small amount of potassium and calcium (4 mEq/L each). It is ideal for the replacement of acute fluid losses where serum electrolyte concentrations are initially normal. Normal renal function usually ensures that any extra free water from this solution is excreted. Hyponatremia can occur with extended use of lactated Ringer solution. Furthermore, the presence of potassium in lactated Ringer solution has been a concern when used in patients with acute kidney injury, although more recent data has suggested that normal saline (with no potassium in solution) may actually be more likely to cause hyperkalemia in this population due to metabolic acidosis-induced cellular shifts of potassium from the cell. Although the lactate anion in lactated Ringer solution is metabolized to bicarbonate in the liver, this does not appear to contribute to acidosis in normal hepatic function. Work comparing the D,L-racemic mixture of lactate has implicated the D-isomer in leukocyte activation.¹⁶ There are no compelling data to suggest that resuscitation with

this solution increases the inflammatory response. Utilization of only the L-isomer is presumed to eliminate this concern.¹⁶ Ringer solution is not used as a diluent in blood transfusions given the concern of calcium being chelated by citrate (an anticoagulant in blood products), which may promote clotting in donor blood.

For maintenance fluid therapy especially prior to an operation with *nil per os* status or following correction of any existing deficits, less concentrated saline solutions are more appropriate to replace ongoing fluid losses (e.g., nasogastric tube losses). The specific crystalloid selected is best determined by calculated requirements. These fluids are hypoosmotic and hypotonic with respect to plasma. In theory, rapid infusion of very hypotonic solutions can result in red blood cell lysis. For this reason, 5% dextrose (50 g of dextrose per liter) has traditionally been added to these solutions to increase tonicity. The addition of dextrose is beneficial in pediatric patients who are unable to adequately control glucose homeostasis due to immature livers. A 5% dextrose solution represents 200 kcal per liter of solution.

Hypertonic saline solutions (HTSs) (3% NaCl and 5% NaCl) are generally used to replace sodium deficits in patients with symptomatic hyponatremia. These and even more concentrated (7.5% and 23% NaCl) solutions have also been used for resuscitation of hemorrhagic shock, head trauma, and burn patients.^{17–19} Hypertonic saline appears to increase intravascular volume in these patients more quickly than isotonic solutions. It is believed that the osmotic gradient produced redistributes fluids from the perivascular and intracellular spaces to the intravascular space with consequent plasma volume expansion (up to fourfold). This, in turn, may decrease the total resuscitation volume requirement. When HTS is used for resuscitation of patients with severe sepsis, it has been shown to result in improvements in oxygen transport, cardiac output, and pulmonary capillary wedge pressure.¹⁷ The systemic and mesenteric oxygen extraction coefficient improves without worsening of other markers of perfusion. This is achieved by rapid mobilization of fluids from the intracellular compartment to the extracellular compartment. These cardiovascular and hemodynamic effects are short-lived, in general lasting from 60 to 120 minutes.

The osmotic effect of hypertonic saline may benefit patients with acute severe brain injury.¹⁹ By reducing the water content of the brain, HTS can help to control intracerebral pressure after injury. In addition, HTS has immunomodulatory effects, which are well documented.²⁰ HTS reduces the systemic inflammatory response syndrome and may attenuate multiple organ dysfunction syndrome. HTSs are not without adverse effects, however. Patients are at risk for electrolyte abnormalities such as hypernatremia, hyperchloremia, and consequent metabolic acidosis. Extravasation into the soft tissues can produce significant soft tissue edema and even necrosis.

Colloids

Colloids are composed of large molecules (e.g., albumin) that have a greater tendency to stay in the intravascular space. They appear to be more effective at enhancing the plasma volume than do crystalloid fluids. Colloid solutions offer the potential benefits of promoting fluid retention in the intravascular space and reducing excess interstitial fluid (edema). Worldwide, albumin and artificial colloids are relied on to a varying degree in fluid management of the surgical patient. In the United States, concerns regarding the effectiveness, cost, and potential complications of colloid administration have limited their use to specific clinical situations.

Albumin

Albumin (69 kD) is the primary protein in plasma responsible for oncotic pressure. Exogenous human albumin is derived from human plasma and heat-treated to reduce the risk of infection. It is available in a 5% (50 g/L) and a 25% solution (250 g/L) in isotonic saline. These act by increasing plasma oncotic pressures and theoretically slowing or even reversing movement of water into the interstitial space. Albumin has an approximate intravascular half-life of 4 hours in conditions of normal physiological capillary permeability. However, many of the conditions associated with edema are also associated with abnormalities in microvascular permeability (e.g., systemic inflammatory disease). For example, the pulmonary circulation in the adult respiratory distress syndrome, regional circulatory beds in postoperative patients, burns or infections, and the systemic circulation in sepsis all lead to conditions resulting in increased microvascular permeability. It is, therefore, believed that exogenously administered protein in colloid solutions quickly extravasate into the interstitial space and paradoxically intensify – rather than decrease – interstitial edema. The SAFE trial (Saline vs. Albumin Fluid Evaluation) found no overall difference in organ dysfunction or survival when comparing saline administration to albumin infusion.²¹ However, the SOAP trial (Sepsis Occurrence in Acutely Ill

Patients) demonstrated increased mortality in intensive care unit patients treated with colloids.^{22,23} As mentioned above, albumin solutions are heat-treated to negate viral and bacterial contamination. Allergic reactions are rare. The primary concern with albumin administration is cost; the infection risk is negligible.

Hetastarch

Hydroxyethyl starches (HES) are synthetic colloids derived from hydrolyzed amylopectin. In the United States, it is available as a 6% solution of high-molecular-weight (150 to 450 kD), highly hydroxyethyl substituted HES in normal, isotonic saline. The average molecular weight of the starch molecules is equivalent to that of albumin. However, HES is slightly more effective than 5% albumin as a colloid – it has a higher colloid oncotic pressure than 5% albumin. The main advantage of hetastarch is its lower cost compared to albumin.

Hetastarch has been used as a resuscitative solution in a variety of clinical settings with variable results. Coagulopathy and bleeding complications have been widely reported after administration of highly substituted, high-molecular-weight HES.^{24,25} This appears to be associated with reduced factor VIII and von Willebrand factor levels, a prolonged partial thromboplastin time, and impaired platelet function.²⁶ It also has a long elimination half-life (17 days). Because of its long half-life, the coagulopathy does not rapidly reverse after cessation of HES administration. Also, serum amylase enzymes continually degrade HES molecules before renal clearance. It is common for serum amylase levels to be elevated for the first few days after HES infusion. In order to differentiate this from pancreatitis, serum lipase levels should be checked and are usually normal.

The above observations and reports of renal insufficiency after HES administration prompted a prospective study, with results published in 2012.^{27,28} The results of these trials were so significant that the FDA and the Pharmacovigilance Risk Assessment Committee, the European equivalent of the FDA, recommended suspending marketing authorization of all HES products and issued warnings to its use.^{29,30} The Surviving Sepsis Campaign recommends against HES administration in septic patients.³¹

Dextrans

First introduced in the 1940s, dextrans are glucose polymers synthesized by *Leuconostoc mesenteroides* bacteria. These are available as synthetic plasma expanders in both 40 kD (dextran 40) and 70 kD (dextran 70) solutions. Although neither is used frequently for volume expansion, dextran 70 has been preferred because of its significantly longer half-life and better retention in plasma. It is degraded to glucose and water by cells. The use of dextrans involves risks of anaphylaxis, hyperglycemia, renal dysfunction and failure, coagulopathy (e.g., erythrocyte and platelet dysfunction), and increased thrombosis rates. The use of dextran solutions is no longer favored given a higher relative risk of mortality compared to HESs.³²

Gelatins

Gelatin solutions produced from bovine collagen are effective as plasma volume expanders. These are currently only available outside the United States in urea-linked (Gelofusin) and succinate-linked (Haemaccel) formulations. Gelofusin has been used in similar clinical settings to HES, with similar clinical results.³³ Uniquely, coagulopathy does not appear to be an issue with gelatins. Renal impairment has been reported with these colloids as having allergic reactions ranging in severity from pruritus to anaphylaxis with both gelatin formulations.³⁴

Artificial Oxygen Carriers

Recent clinical trials and subgroup analyses using temporary hemoglobin-based oxygen-carrying solutions (e.g., PolyHeme, Northfield Laboratories, Inc.) have been encouraging albeit with some controversy.³⁵ PolyHeme is made from polymerized human hemoglobin. It originally began as a military project following the Vietnam war. PolyHeme's primary use is in trauma situations with massive blood loss when fresh, whole blood is not readily available for transfusion. On May 9, 2009, Northfield Laboratories, Inc. shut down operations after it failed to secure a biologic license application for PolyHeme from the FDA. However, with further studies, solutions like PolyHeme may prove beneficial in the future when volume expansion in conjunction with increased oxygen-carrying capacity is required.

GOALS OF FLUID AND ELECTROLYTE THERAPY

Maintaining homeostasis – body fluid and electrolyte concentrations – and normal hemodynamic parameters are the goals of fluid and electrolyte therapy. This is accomplished by first understanding the general maintenance fluid required by an idealized 70-kg male patient to account for normal daily losses. Thereafter, it is imperative to correct existing volume and electrolyte abnormalities and any ongoing losses associated with disease states and surgical treatments.

Table 11-5 Calculation of Maintenance Fluid Requirements

Body Weight	Fluid Requirement ^a	
For 0–10 kg	Give 100 mL/kg/day	A
For the next 10–20 kg	Give an additional 50 mL/kg/day	B
For weight >20 kg ^b	Give 20 mL/kg/day	C

^aMaintenance fluid requirements = A + B + C.
^bFor elderly patients or patients with cardiac disease, this amount should be reduced to 15 mL/kg/day.

Maintenance Fluid Therapy

Maintenance fluid volume requirements can be calculated based on body weight taking into account a larger per kilogram volume requirement of smaller body weight individuals (Table 11-5). A 10-kg child requires 100 mL/kg/day or 1,000 mL/day. A 70-kg man requires 1,000 mL/day for the first 10 kg (100 mL/kg × 10 kg), plus 500 mL/day for the second 10 kg (50 mL/kg × 10 kg), plus 1,000 mL/day for the last 50 kg (20 mL/kg × 50 kg), for a total daily water requirement of 2,500 mL/day. In patients who may be intolerant of hypervolemia (i.e., cardiac disease, elderly patients), the requirement per kilogram over 20 kg is decreased to 15 mL/kg/day.

Maintenance Electrolyte Therapy

One to 2 mEq/kg/day of sodium is required, with any administered excess managed by urinary sodium excretion. Potassium requirements are approximately 0.5 to 1 mEq/kg/day. If sodium is replaced at 2 mEq/kg/day and potassium is replaced at 1 mEq/kg/day, a 70-kg patient requires 2,500 mL of water containing 140 mEq of sodium and 70 mEq of potassium. Each liter of parenteral solution would contain 56 mEq of sodium and 28 mEq of potassium. The solution that best fits this patient’s daily maintenance requirements is 0.33% saline solution (56 mEq/L Na⁺). Potassium chloride can be added to each liter of solution (20 to 30 mEq/L), with appropriate adjustments for the patient’s electrolyte and renal functional status.

Additional Electrolyte Therapy

Short-term maintenance therapy generally does not require addition of calcium, phosphate, or magnesium. In patients with acute and/or chronic disorders, patients who experience significant volume shifts, or patients who require long-term parenteral fluid therapy, these electrolytes should be measured and corrected by the most practical, physiologically natural route. In general, the enteral route is preferred given normal physiology. If the enteral route is unavailable, these additional electrolytes are administered in parenteral nutrition solutions along with trace elements, vitamins, and appropriate caloric sources. Corrections and allotment must be made for disease states that may alter the need or absence of electrolytes (e.g., potassium in renal failure patients) in replacement solutions.

CORRECTION OF VOLUME ABNORMALITIES

Volume Deficits

States of subphysiologic volume (i.e., hypovolemia) are common among surgical and trauma patients. This may be related to direct blood loss or other fluids. Large volumes of fluid can be sequestered in extravascular spaces (third-space losses) as a consequence of inflammation, sepsis, or shock-related endothelial injury and increased endothelial permeability.³⁶ This situation is characterized by a movement of proteins and fluid from the intravascular to the interstitial compartment. Examples of disorders that cause third-space losses include bowel obstruction with edema of the bowel wall and

transudation of fluid into the bowel lumen, pancreatitis (especially with retroperitoneal fluid extravasation) and extensive tissue destruction in trauma. While the disease state exists, normal homeostasis is altered and cannot be maintained. With the resolution of the pathologic condition and normalization of microvascular permeability, these fluid losses abate. Sequestered extravascular fluid returns – albeit at variable rates – to the intravascular space.

Volume deficits can manifest either acutely or over time. Chronic volume deficits may manifest with decreased skin turgor, sunken eyes, oliguria, weight loss, hypothermia, tachycardia, and orthostatic hypotension. In addition, serum BUN and creatinine values may be elevated, with a high BUN/creatinine ratio (above 15:1). The absolute hematocrit level has been shown to be a poor predictor of intravascular volume status. The hematocrit may be measured during dialysis as a way to indirectly measure volume status.³⁷ Optical measurements of absolute red cell mass and oxygen saturation are measured as blood passes through the dialysis tubing while a patient is undergoing dialysis treatment. The hematocrit is then determined by both the absorption properties of hemoglobin and the scattering properties of red blood cells passing through the blood chamber.³⁷

Acute volume losses usually manifest by changes in vital signs. In an attempt to provide sufficient cardiac output for end-organ perfusion, the heart rate may increase. At the extreme, blood pressure will drop resulting in hypotension. Urine output is usually low by this point.

Fluid resuscitation for hypovolemia is initiated with an isotonic solution such as normal saline or lactated Ringer solution. Once routine laboratory values (e.g., chemistries) are measured, tailoring the type of solution can be done. Urine flow in critically ill patients is monitored with an indwelling Foley catheter with a goal of at least 0.5 mL/kg/hr output. In addition, a thorough history and physical examination will help determine the origins of the volume deficits, specifically addressing underlying causes and resultant losses.

Volume Excess

Volume excess may occur with significant resuscitative fluid, blood product administration, or excessive parenteral volume administration. Volume overload will occur if adjustments to fluid therapy are not made as the clinical status of the patient changes. Possible manifestations of volume overload are weight gain, truncal and peripheral edema and pulmonary congestion (identified by rales on pulmonary auscultation and/or radiographic chest imaging). Intravascular volume excess is treated by a combination of volume restriction and diuresis. At the extreme, volume overload may be treated by ultrafiltration of the blood (often done concurrently during hemodialysis).

REPLACEMENT OF ONGOING FLUID LOSSES

Ongoing losses from stomas, fistulae, open body compartments (e.g., abdomen, chest) and all tubes (e.g., nasogastric) and drains – are recorded during the course of care. Once the net “ins and outs” have been calculated, any existing volume deficits should be replaced with fluid replacement. The electrolyte content of these fluids can be estimated or measured and used to guide the choice of replacement fluid type (Table 11-6). As the disease state changes, the overall fluid balance of the patient can be estimated and replaced beyond what is considered to be maintenance.

Table 11-6 Electrolyte Concentrations in Gastrointestinal Secretions

Secretion	Electrolyte (mEq/L)					Rate (mL/day)
	Na ⁺	K ⁺	Cl ⁻	...	H ⁺	
Salivary	50	20	40	30	—	100–1,000
Gastric						
Basal	100	10	140	—	30	1,000
Stimulated	30	10	140	—	100	4,200
Bile	140	5	100	—	—	500–1,000
Pancreatic	140	5	75	—	—	1,000
Duodenum	140	5	80	—	—	100–2,000
Ileum	140	5	70	—	—	100–2,000
Colon	60	70	15	—	—	—

Intraoperative Fluid Therapy

Fluid losses during operative procedures result from evaporative losses in open wounds, blood loss, and extravascular, third-space sequestration. Relative operative blood loss can frequently be measured. Evaporative losses as well as shifts of intravascular fluid to the extravascular space are difficult to measure, but should be anticipated. Intraoperative replacement with crystalloid solutions is usually accomplished at rates of 500 to 1,000 mL/hr as this is roughly equivalent to the hourly insensible loss rate during open celiotomy cases. The choice of intraoperative fluid is dependent on many factors. Administration of buffered solutions (e.g., Ringer lactate solution) is as efficacious and safe as nonbuffered, saline-based fluids and may prevent postoperative hyperchloremia and metabolic acidosis. Close monitoring of blood pressure, blood loss, urine output, and invasive monitoring techniques aids the surgeon and anesthesiologist in gauging fluid shifts and potential problems associated with intraoperative volume depletion.

Postoperative Fluid Therapy and Monitoring

Routine monitoring of intraoperative and postoperative fluid status consists of serial vital signs (e.g., blood pressure and heart rate), measurements of all tubes, lines, and drains (e.g., urine output) and inclusive of all intravenous and enteral drips. These are recorded in the patient's medical record and used to plan ongoing fluid management. The net gains (all inputs) minus the losses allow daily and length-of-stay volume assessments to be made. Daily weight should also be recorded and compared to the patient's starting or "dry" weight prior to their surgery, if possible. In the postsurgical patient, rapid fluctuations in weight are generally related to changes in TBW. In the absence of any extenuating circumstances (e.g., renal dialysis, kidney transplantation), adequate fluid is usually given to maintain a urine output of greater than 0.5 mL/kg/hr in adult patients.

Urine specific gravity can also be measured and serves as an indicator of both volume status and renal ability to concentrate and dilute the urine. A urine specific gravity of greater than 1.010 to 1.012 indicates that the urine is being concentrated (relative to plasma), and a urine specific gravity of less than 1.010 indicates that dilute urine is being produced.

Renal failure in the postoperative period may be accompanied by low urine volume (oliguric renal failure, <0.5 mL/kg/hr, or <500 mL/day). Additionally, normal or high urine volumes (nonoliguric or high-output renal failure) may also indicate renal dysfunction. Measuring the fractional excretion of sodium compared to creatinine (i.e., FeNa) can help delineate the potential etiology of renal dysfunction by discerning prerenal states (FeNa usually <1%) from acute tubular necrosis (FeNa usually >2%).

$$\text{FeNa} = (\text{Urine}_{\text{Na}})(\text{Serum}_{\text{Creat}})/(\text{Urine}_{\text{Creat}})(\text{Serum}_{\text{Na}})$$

Central venous pressures (CVPs) have also been extensively used to gauge fluid status and responsiveness. Normal CVP may range from 5 to 12 mm Hg. Higher pressures usually indicate volume overload or cardiac failure, whereas pressures below this range indicate intravascular volume depletion. However, the use of CVP measurements alone has been shown to be highly variable and inaccurate in assessing intravascular volume and venous return. This is especially true in critically ill patients where abnormalities of cardiac performance and vascular tone may confound interpretation of CVP measurements.

More recently, assessments of fluid status, responsiveness, and overall tissue perfusion are being accomplished by the use of (1) bedside echocardiography (e.g., transthoracic) to measure function through ventricular filling and ejection, (2) ultrasound of the vena caval diameter, and (3) peripheral arterial pulse-volume variability calculations. The latter measures the stroke volume variability (SVV) during the ventilatory cycle via a peripherally placed arterial line. SVV is the calculated percentage of the difference between the maximal and minimal stroke volumes (SVs) divided by the mean SV. This is usually calculated over a time period between 20 to 30 seconds.³⁸ Use of the SVV has been shown to be a reliable indicator of fluid responsiveness.

It is important to note that the efficacy of these techniques may be altered in abnormal right and/or left ventricular compliance, increased intrathoracic pressure (via elevated levels of positive end expiratory pressure and intra-abdominal pressure), valvular heart disease (e.g., mitral stenosis) and cardiac dysrhythmias (e.g., atrial fibrillation). In order to solve any serious questions of volume status, the gold standard technique remains pulmonary artery catheterization in the critically ill patient.

ELECTROLYTES

8 An electrolyte is defined as a substance that ionizes when dissolved in an appropriate solvent, the

most common example being water. Some of the most common physiologic electrolytes include: sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺), magnesium (Mg²⁺), chloride (Cl⁻), and hydrogen phosphate (HPO₄²⁻). The + or – designates the charge of the ion.

In order to maintain homeostasis, the human body has a complex yet stable arrangement of electrolytes in different concentrations in the intracellular and extracellular environments (Table 11-7). In clinical practice, only measurements of serum values (extracellular space excluding the interstitial space) are performed and used to infer disruptions of homeostasis, which cause organ damage. For instance, with hyperkalemia, the serum concentration itself does not directly cause injury. It initiates depolarization leading to impairment of cardiac conduction resulting in an end pathway of ventricular fibrillation or asystole.

Given that serum derangements can only be discovered if lab evaluation or symptoms are present, it is important to try to anticipate potentially life-threatening electrolyte abnormalities. This is especially important in surgical patients in whom the loss of electrolyte-rich GI fluids occurs and can cause predictable serum derangements (Table 11-8). For example, an infant with hypertrophic pyloric stenosis who vomits nonbilious gastric secretions will develop a predictable hypochloremic metabolic alkalosis due to the loss of hydrochloric acid. It is therefore of the utmost importance to recognize circumstances that cause predictable electrolyte derangements in order to decrease the risk of morbidity and mortality.

Table 11-7 Electrolyte Concentrations in Plasma and Intracellular Compartments

Normal Ranges		
Solute (mEq/L)	Plasma	Intracellular
Na ⁺	135–145	10–15
K ⁺	3.5–5.0	120–150
Ca ⁺⁺	2.5 (8.5–10.5 mg/dL)	0.0001–10 ⁻⁷
Mg ⁺⁺	1.3–1.9	7
Cl ⁻	98–110	3–20
HCO ₃	22–28	10–15
pH	7.37–7.43	7.0–7.2
Osmolarity	280–290	280–290

Where Sodium Goes, Water Follows

Although the relationship between sodium and water is far more complex than the above adage, there is a distinct correlation between sodium and fluid status. This relationship can help establish both the etiology and treatment of various derangements. For example, when thinking about hyponatremia, it is clinically important to assess the patient’s volume status as well as check laboratory studies. These include serum sodium, serum osmolality, and urine electrolytes. Other values such as serum glucose, serum protein, and serum lipids may also help to differentiate hyponatremia from pseudohyponatremia.⁴⁰

Pseudohyponatremia

Marked elevations in serum lipid or protein result in a reduction in the fraction of serum that is water/sodium and thus causes a “dilutional” hyponatremia. Examples include hyperlipidemia, hyperproteinemia (e.g., multiple myeloma), hyperglycemia, and mannitol administration. In the case of hyperglycemia, the serum sodium concentration should fall 1.6 mEq/L for every 100 mg/dL rise in serum glucose concentration.

Hyponatremia

The most common pathophysiology is retention of water, which most commonly stems from oral intake or iatrogenic use of intravenous hypotonic fluid. The body has an innate ability to produce up to 10 L/day of urine, providing an enormous range of protection against the development of hyponatremia. However, in most surgical/trauma patients who experience hyponatremia, there is an inability to suppress ADH, as it is normally elevated during a stress response. In this case the sodium rarely falls below 130 mEq/L because the hyponatremia itself, as well as volume expansion, decreases the effects of ADH on the renal collecting tubules.

Table 11-8 Electrolyte Concentrations in Gastrointestinal Secretions

Secretion	Na ⁺	K ⁺	Cl ⁻	H ⁺	Rate (mL/day)
Salivary	50	20	40	—	100–1,000
Gastric					
Basal	100	10	140	30	1,000
Stimulated	30	10	140	100	4,200
Bile	140	5	100	—	500–1,000
Pancreatic	140	5	75	—	1,000
Duodenum	140	5	80	—	100–2,000
Ileum	140	5	70	—	100–2,000
Colon	60	70	15	—	—

In significant cases (i.e., serum sodium <130 mEq/L) it is helpful to take a more systematic approach. This entails assessing serum and urine osmolality as well as urine sodium ([Algorithm 11-1](#)).

Symptoms of hyponatremia occur in multiple organ systems including the CNS, GI, and musculoskeletal ([Table 11-9](#)). In acute hyponatremia, symptoms often start when serum sodium is less than 130 mEq/L; whereas in chronic hyponatremia symptoms typically do not occur until serum sodium is less than 120 mEq/L.

Treatment. Treatment depends on the patient's volume status. Hypovolemic patients are treated by rehydration with isotonic saline, with caution not to correct serum sodium faster than 0.5 mEq/L/hr and less than 10 mEq/L over 24 hours. If correction is faster than this rate the patient may develop *central pontine myelinolysis*. This can lead to “locked in” syndrome, which consists of quadriplegia, dysarthria, and dysphagia. In order to best prevent this rare, yet highly morbid complication, use of the following calculation is recommended:

$$\text{Na}^+ \text{ required (in mEq)} = (\text{Desired Na}^+ - \text{Actual Na}^+) \times \text{TBW}$$

$$\text{TBW} = 0.6 \times \text{Weight (kg)}$$

Rapid correction with 3% or higher-concentration solutions should be avoided unless significant CNS symptoms such as coma or seizures are present and should be done using the calculation above to prevent overcorrection. A reasonable initial dose in an emergent situation would be 100 mL of 3% saline given as a bolus; this can be repeated in 10 minute intervals with definite need for follow-up laboratory evaluation to prevent overly rapid correction.

Cerebral Salt Wasting and Syndrome of Inappropriate Antidiuretic Hormone

Cerebral salt wasting (CSW) and syndrome of inappropriate antidiuretic hormone (SIADH) are both seen in the setting of CNS disease, which is especially pertinent to trauma patients. CSW is much rarer and typically occurs within the first 10 days of CNS insult/injury. The pathophysiology is likely related to impaired sodium reabsorption leading to volume depletion, followed by increased ADH release causing hyponatremia from water retention. Laboratory findings are nearly identical amongst CSW and SIADH. Both have elevated urine osmolality compared to serum. However, CSW is associated with ECF depletion and thus hypotension and/or elevated hematocrit, whereas SIADH patients are often net positive in fluid balance. Given the volume status associated with CSW the treatment is usually isotonic fluids which will suppress the release of ADH. On the contrary if isotonic fluid is given for SIADH it can actually worsen the hyponatremia. Other options to treat CSW include salt tablets and if needed fludrocortisone.

The initial treatment for SIADH is often fluid restriction of <800 mL/day. For more significant cases the use of oral salt tablets or 3% hypertonic saline is recommended. Finally, vasopressin receptor antagonists such as Conivaptan (IV) and Tolvaptan (PO) can be used; however these do carry risks such as hepatotoxicity and can rapidly overcorrect serum sodium levels. Furthermore, they are fairly expensive in the United States and hence should only be used in select cases.^{39–41}

Algorithm 11-1

Algorithm 11-1. Hyponatremia.

Hypernatremia

Although a less common problem in surgical patients, hypernatremia has a variety of etiologies which, like hyponatremia can be categorized based on the patient's volume status (Table 11-10). The most common scenario is excessive free water loss associated with hypovolemia.

Symptoms of hypernatremia typically do not develop until serum sodium exceeds 160 mEq/L or serum osmolality is higher than 320 to 330 mOsm/kg. Also, akin to hyponatremia the degree of acuity is a factor. Acute hypernatremia can cause symptoms at lower levels than chronic hypernatremia. The majority of symptoms experienced are CNS related with early signs being irritability, restlessness, and spasms. Later symptoms include ataxia and seizures.

The treatment of hypernatremia, like hyponatremia should not occur too rapidly, otherwise complications can ensue. A rate >0.7 mEq/L is considered dangerous as it can lead to cerebral edema and brainstem herniation. The most judicious way to correct hypernatremia involves calculating the free water deficit to obtain a desired sodium level.

Table 11-9 Symptoms of Hyponatremia

Central nervous system	Headaches Confusion Delirium Coma Seizures
Gastrointestinal	Anorexia Nausea Vomiting
Musculoskeletal	Weakness Fatigue Muscle cramps

$$\text{Water requirement} = (\text{Desired change in Na}^+ \times \text{TBW}) / \text{Desired Na}^+$$

$$\text{TBW} = 0.6 \times \text{Weight (kg)}$$

A caveat to this equation is that it does not take into account ongoing free water losses such as urinary or GI loss. Further calculations can be done to quantify urine losses if this is a major concern.

Table 11-10 Causes of Hypernatremia

Volume Status	Cause
Low	Free water loss Insensible—skin, respiratory Gastrointestinal loss Excessive hyperosmotic peritoneal dialysis Renal: diuretics, diabetes insipidus, nonoliguric renal failure
Normal	Same as “Low” volume status but with improper correction
High	Free water loss Increased mineralocorticoids—hyperaldosteronism, hypercortisolism Iatrogenic Excessive sodium administration

Algorithm 11-2. Acute hyperkalemia.

Potassium

Potassium is the most abundant intracellular cation with a normal intracellular concentration of 150 mEq/L as opposed to an extracellular level ranging from 3.5 to 5 mEq/L. This large gradient produces a strong membrane potential especially in cardiac, skeletal, and smooth muscles. The overall potassium balance is determined by potassium intake and renal/extrarenal excretion. Renal excretion accounts for 90% of excreted potassium. Thus, renal failure leads to hyperkalemia. Humoral factors such as aldosterone, vasopressin, and β -agonists stimulate renal excretion of potassium. Intracellular shifting is another strong causative agent for extracellular potassium change. For instance, insulin and alkalosis both cause K^+ to shift intracellular, one for glycolysis, the other in exchange for H^+ as a buffer. Conversely, acidosis causes K^+ to shift extracellular in exchange for H^+ , again to buffer serum pH.

Hyperkalemia

Renal insufficiency is the leading cause of hyperkalemia in surgical patients. Hyperkalemia can occur even in the setting of nonoliguric renal failure. Potassium-rich intravenous fluids, especially blood transfusions can also lead to hyperkalemia. Disease processes associated with cellular injury such as crush injuries, reperfusion syndrome, tumor lysis syndrome, and burns are all potential causes of hyperkalemia. Additionally, medications such as succinylcholine and ACE inhibitors can worsen existing hyperkalemia.

Regardless of the etiology, the common pathway for clinical manifestations is dysfunctional membrane depolarization, the most lethal scenario effecting cardiac membrane depolarization. On an electrocardiogram (EKG) this can be seen in the mildest form with peaked T waves, in a more severe state with flattened P waves, prolongation of the QRS, or deep S waves. The final pathway can yield ventricular fibrillation with or without cardiac arrest.

The initial medication of choice for hyperkalemia is intravenous calcium for membrane stabilization, which lasts approximately 30 to 60 minutes. Subsequent therapy can include insulin coadministered with dextrose, β_2 agonist, and sodium bicarbonate, which are designed to shift extracellular potassium

into the intracellular space. Resin-binding agents such as Kayexalate act to decrease potassium absorption and thus are more important in the management of chronic hyperkalemia.^{42,43} Loop diuretics can assist by promoting renal potassium excretion, but should only be used if the patient is not hypovolemic. A last resort in situations of complete renal failure or critical levels of potassium is hemodialysis. The treatment utilized depends upon the laboratory value, but more importantly the clinical scenario and EKG findings (Algorithm 11-2).

Hypokalemia

Similar to hyperkalemia, manifestations of hypokalemia result from the disturbance in the gradient between intracellular and extracellular potassium. The reference level of 3.5 mEq/L is often cited as the lowermost level of normal serum potassium. Below this level minor disturbances including intestinal ileus, premature ventricular complexes, and nonfatal arrhythmias can occur. Severe cardiac and muscle manifestations often do not occur until levels fall below 2.5 mEq/L. Findings at this dangerous level include significant muscle weakness and major EKG changes. Possible changes include prolonged QT, flattened T waves, ST depression, prominent U waves, and most dangerously ventricular arrhythmias.

Initial treatment consideration must include elucidation of possible etiologies (Table 11-11); certain etiologies are especially important, as without correction of the underlying cause, the hypokalemia itself may not be correctable. Examples of this include hypomagnesemia, acute alkalosis, hyperaldosteronism, and mucus secreting villous adenoma. The mainstay of initial treatment for hypokalemia is enteral or intravenous potassium replacement. If the patient is symptomatic, then the replacement or at least a portion of it should be given intravenously to achieve a more rapid effect. Limiting the rate of intravenous potassium infusion is necessary to prevent caustic injury to veins. Maximal recommended rates include 10 to 20 mEq/hr via a peripheral IV or up to 40 mEq/hr via central access.

Table 11-11 Causes of Hypokalemia

Major Causes of Hypokalemia
Vomiting/diarrhea
Diuretics (i.e., loop diuretic)
Catecholamines (endogenous or exogenous)
Renal tubular acidosis
Refeeding syndrome
Insulin
Hypomagnesemia
Acute alkalosis

Figure 11-6. Effects of hypocalcemia (A) and hypercalcemia (B) on the mediators of calcium homeostasis. PTH, parathyroid

hormone.

Calcium

Calcium (Ca^{2+}) is essential for human life. Calcium participates in numerous processes including cardiac membrane depolarization, muscle contraction, enzymatic reactions, coagulation, and formation of bone/teeth. Approximately 99% of total body calcium is located in bone. Ionized calcium, which makes up approximately 45% of total calcium, is responsible for most of the physiologic actions of calcium in the body. Normal serum concentration of ionized calcium is approximately 4.5 mg/dL and this level is tightly regulated. Both pH and plasma protein level can affect the proportion of calcium in the ionized state. A change in albumin concentration of 1 g/dL changes protein-bound calcium by 0.8 mg/dL in the same direction. The fundamentals of the regulation of calcium homeostasis are depicted in [Figures 11-6](#) and [11-7](#). The effect of pH on calcium will be discussed later in this chapter.

Hypercalcemia

The most common causes of hypercalcemia are hyperparathyroidism and malignancy ([Table 11-12](#)).^{44,45}

Primary hyperparathyroidism occurs when one or more parathyroid glands inappropriately produce increased amounts of PTH. Parathyroid adenomas are responsible for ~85% of cases. Chief cell hyperplasia accounts for an additional 15% of cases, while parathyroid cancer is the cause in less than 1% of cases of primary hyperparathyroidism.

Secondary hyperparathyroidism occurs when there is elevated PTH due to another organ system, namely renal failure. This occurs because of poor renal excretion of phosphate and decreased intestinal absorption of calcium secondary to impaired renal hydroxylation of vitamin D.

Tertiary hyperparathyroidism is parathyroid hyperplasia with autonomous PTH production. Most commonly, patients who had renal failure with secondary hyperplasia then undergo renal transplant and still have hypercalcemia. This occurs in up to 30% of patients with prerenal transplantation hyperparathyroidism ([Table 11-13](#)).

Figure 11-7. Vitamin D synthesis.

Table 11-12 Other causes of Hypercalcemia

PTH mediated	Lithium Familial hypocalciuric hypercalcemia (FHH)
Cancer	PTHrp-mediated breast, lung, renal cancer Bone metastases Multiple myeloma
Calcitriol mediated	End-stage renal disease Sarcoid/granulomatous Lymphoma (ectopic 1,25 vit D) Milk alkali syndrome Exogenous vitamin D
Other causes	Vitamin A toxicity Thyrotoxicosis Paget disease Adrenal insufficiency Medications (i.e., Thiazide)

Regardless of cause, hypercalcemia has characteristic clinical manifestations that affect various organ systems. Classically taught as “stones, moans, and psychiatric undertones,” meaning renal, abdominal/GI, and neuropsychiatric manifestations ([Table 11-14](#)). The earliest symptoms are usually

neuromuscular and mild GI symptoms. Cardiac and renal complications typically occur later in disease progression.

Treatment. Serum calcium concentration >14 mg/dL requires prompt treatment. If combined with hyperphosphatemia, this situation is even more concerning due to the potential for metastatic calcification. Initial treatment should include aggressive hydration with 0.9% normal saline with 20 mEq/L potassium with a goal of hydration to promote a urine output greater than 200 mL/hr. Once the patient is adequately hydrated a trial of furosemide can be performed as long as a positive fluid balance is maintained and potassium and magnesium are adequately replaced. Other adjuncts include calcitonin (especially for inhibition of bone resorption), bisphosphonates (especially to treat malignancy), and in patients with renal failure the use of low-calcium dialysate. Patients with hematologic malignancies and granulomatous disease can be considered for treatment with steroids. Lastly, for those with hyperparathyroidism, parathyroidectomy of some form is clearly indicated, with operation type dependent upon whether the etiology is adenoma or hyperplasia. In medically refractory secondary or tertiary hyperparathyroidism, total parathyroidectomy with parathyroid autotransplantation or sub-total parathyroidectomy should be considered.⁴⁶

Hypocalcemia

There are many causes of hypocalcemia (Table 11-15). Other factors can affect the serum calcium level as mentioned previously, namely pH and albumin. In critically ill patients the incidence of hypocalcemia can be up to 85%. From a surgical perspective the most common causes are postsurgical, including hungry bone syndrome and loss of calcium from circulation.

Table 11-14 Signs and Symptoms of Hypercalcemia

Constitution symptoms	Weakness, fatigue, anorexia
CNS	Drowsiness, lethargy, altered mental status, stupor, coma
Cardiac	Short QT interval
Renal	Nephrolithiasis, polyuria, renal failure, nephrogenic diabetes insipidus, nephrocalcinosis
GI	Constipation, abdominal pain, pancreatitis
Ophthalmologic	Calcium deposits in cornea

Postsurgical hypocalcemia can occur in any neck surgery, although the incidence is higher with parathyroidectomy. In non-neck surgery hypocalcemia can occur because of hypoalbuminemia; this does not affect ionized calcium levels. Other postsurgical causes of hypocalcemia include atrophy of the remaining parathyroid glands (i.e., after removal of a large parathyroid adenoma), venous congestion, devascularization or *hungry bone syndrome*. Transient hypoparathyroidism is seen in up to 20% of thyroid cancer surgery; this is permanent in 1% or less of cases.

Other surgery-related etiologies include pancreatitis, small bowel fistula, renal failure, massive transfusion of blood, and severe hypomagnesemia. Pancreatitis-induced hypocalcemia occurs due to calcium precipitation in peripancreatic tissue. Small bowel fistula can lead to hypocalcemia by loss of calcium-rich effluent and vitamin D deficiency from malnutrition. Renal failure hypocalcemia is due to deficiency in 1,25-dihydroxyvitamin D and hyperphosphatemia. Massive transfusion hypocalcemia does not affect total calcium but decreases ionized calcium as a result of citrate binding to ionized calcium.

Symptoms typically do not occur until calcium levels are below 8 mg/dL. Chronic symptoms include cataracts, dental changes, and extrapyramidal disorders. Symptoms of acute hypocalcemia are tetany, papilledema, and seizures. Tetany is defined as repetitive discharges after a single stimulus. Tetany usually does not occur until ionized calcium is less than 4.3 mg/dL or serum total calcium is less than 7.0 mg/dL. Alkalosis also plays a strong role in the development of tetany, even beyond its association with hypocalcemia, as tetany is rarely seen in renal failure patients despite low calcium levels. This is likely due to the protective effect of concurrent metabolic acidosis. The earliest symptoms of hypocalcemia are perioral and acral paresthesias. Motor symptoms such as *Trousseau sign* (induction of carpopedal spasm by inflation of sphygmomanometer above systolic pressure for 3 minutes) and *Chvostek sign* (tap facial nerve and ipsilateral facial muscles twitch) occur later. Of note, Chvostek sign is seen in up to 10% of normal patients. The last findings to occur are cardiac, in the form of ST segment

prolongation (Table 11-16).⁴⁴

Table 11-13 Differential Diagnosis of Hypercalcemia

Cause	Ca ⁺	Phos	PTH	24 hr UCa
Primary PTH	Increased	Decreased	Elevated/normal	Elevated
Secondary PTH	Low or normal (can be high w/ prolonged disease)	High	Elevated	N/A
FHH	Increased	Normal	Elevated/normal	Decreased
PTHrp mediated	Increased	Decreased	Decreased	Elevated
Tertiary PTH	Increased	Decreased	Very Elevated	Elevated

PTHrp, parathyroid hormone-related peptide; UCa, urine Ca⁺.

Table 11-15 Causes of Hypocalcemia

Low PTH (hypo-parathyroidism)	Postsurgical (thyroidectomy, parathyroidectomy, radical neck dissection, hungry bone syndrome) Autoimmune Infiltration of the parathyroid gland (granulomatous, iron overload, metastases) Radiation-induced destruction parathyroid glands HIV infection
High PTH (secondary hyperparathyroidism in response to hypocalcemia)	Vitamin D deficiency Pseudohypoparathyroidism Hypomagnesemia Renal disease Loss of calcium in circulation (i.e., hyperphosphatemia, tumor lysis, acute pancreatitis, osteoblastic metastases, acute respiratory alkalosis, sepsis)
Drugs	Bisphosphonate, calcitonin, phenytoin, foscarnet, calcium chelators

Asymptomatic hypocalcemia needs no treatment as it is most commonly attributed to hypoalbuminemia with normal ionized calcium. Symptomatic hypocalcemia is best treated with intravenous infusion of calcium gluconate or calcium chloride. Calcium chloride is faster acting as it does not require hepatic metabolism to dissociate into an active form, hence is usually the drug of choice if severely symptomatic. A study during the anhepatic stage of liver transplantation found equally rapid increase in calcium after administration of calcium chloride and gluconate.⁴⁷ Calcium chloride carries a higher risk of irritation of veins and tissue damage should extravasation occur; hence calcium gluconate should be the drug of choice except in emergent situations. In order to minimize caustic damage to veins, any form of calcium should be administered at a rate not to exceed 1.5 mEq/min. If prolonged calcium replacement is needed it is recommended to check vitamin D levels and replace any deficiency with calcitriol, in addition to giving an oral form of calcium such as calcium carbonate, calcium citrate, or calcium lactate.

Table 11-16 Clinical Manifestations of Hypocalcemia

Acute	Neuromuscular Paresthesia (initially perioral) Seizures Tetany (i.e., Trousseau/Chvostek sign) Pulmonary Laryngospasm, bronchospasm Cardiac Prolonged QT, hypotension, heart failure, arrhythmias Ocular Papilledema
Chronic	Abnormal dentition Extrapyramidal signs Ectopic calcification Subcapsular cataracts

Magnesium

Half of the total body magnesium is confined to bone. Most of the remaining magnesium is intracellular, with less than 1% of total body magnesium found extracellular. Magnesium is primarily absorbed in the small intestine and is influenced by 1,25-dihydroxyvitamin D3. The other source of magnesium is bone.

Hypermagnesemia

Outside of renal failure, hypermagnesemia is rare, as the kidneys have a strong ability to excrete large amounts of magnesium. Instances do occur with severe burns, crush injuries, or other causes of rhabdomyolysis but usually in the setting of renal insufficiency. Symptoms of hypermagnesemia include loss of deep tendon reflexes at levels greater than 8 mg/dL. Once levels are greater than 12 mg/dL paralysis can occur. Cardiac arrest can occur if levels exceed 18 mg/dL. The mainstay of treatment is intravenous calcium to antagonize the effect of magnesium, volume expansion or loop diuretic depending on volume status, correction of acid–base disturbances and if needed, hemodialysis.

Hypomagnesemia

Kidneys are also able to conserve magnesium quite well with about 40% reabsorption in the proximal tubule. Most instances of hypomagnesemia occur with chronic malnutrition, prolonged intravenous fluid replacement without magnesium, and loop diuretics. Other causes include pancreatitis and diabetic ketoacidosis (DKA). Magnesium functions as a cofactor for many neuromuscular functions, thus deficiency can lead to muscle fasciculation or tetany. The treatment depends on the severity, which includes taking into account symptoms and magnesium level. For instance, if serum magnesium level is less than 1 mEq/L or if the patient is hemodynamically unstable or is in a torsade de pointes arrhythmia then immediate infusion of intravenous magnesium sulfate is indicated. The maximum recommended rate would be 150 mg/min excluding the above emergent situations where it can be given as IV push or over 5 minutes for torsade de pointes. If the patient has chronic or mild hypomagnesemia, oral doses of magnesium should be used, with options including magnesium oxide, magnesium chloride, and magnesium hydroxide (milk of magnesia) depending on side-effect profiles. It should be noted that doses greater than 80 mEq/day can become cathartic.

ACID–BASE

An acid is defined as a chemical that can donate a hydrogen ion (H⁺), for example, HCl and H₂CO₃. A base is a chemical that can accept an H⁺, for example, OH[–] and HCO₃[–]. Ampholytes are both acids and bases; an example is H₂PO₄[–], which can donate an H⁺ to become HPO₄^{2–} but can also accept H⁺ to become H₃PO₄. Bases are commonly anions, but neutral substances can also function as bases (e.g., ammonia and creatinine). Some chemicals do not fit the classic definition of an acid, although they retain acidic properties when dissociated in water. For example, when CaCl₂ is dissolved in water, the Ca²⁺ accepts OH[–] to form Ca(OH)₂.

The concentration of hydrogen ions [H⁺] determines the acidity of a solution. The pH is the negative logarithm of [H⁺] expressed in moles per liter (mol/L). The concentration of H⁺ in biologic systems is in the range of nanomoles (10^{–9} mol) per liter (nmol/L). The degree to which an acid dissociates determines its strength.

Table 11-17 HCO₃[–] and PCO₂ Derangements in Primary and Secondary Acid–Base Disturbances

Disorder	pH	Primary		Secondary	
		HCO ₃ [–]	PCO ₂	HCO ₃ [–]	PCO ₂
Metabolic acidosis	↓	↓			↓
Metabolic alkalosis	↑	↑			↑
Respiratory acidosis	↓		↑	↑	
Respiratory alkalosis	↑		↓	↓	

The *Henderson–Hasselbalch* equation describes pH as a measure of acidity in a biologic system.

$$\text{pH} = \text{pK}_a + \log_{10} ([\text{A}^-]/[\text{HA}])$$

pK_a = Negative log of the acid dissociation constant

A⁻ = Conjugate base

HA = Acid–base pair

Buffer Systems

Buffers are chemicals in solution that tend to minimize changes in pH that would otherwise occur after the addition of acid or alkali. For instance, if a strong base is added to a weak acid, the base is neutralized:

One type of buffer is a mixture of a weak acid and its salt. The presence of such buffer systems in the body is crucial in minimizing changes in pH, which can be deleterious to cell function.

The principal intracellular buffers are organic phosphates, bicarbonate, and peptides. In addition, hemoglobin functions as a significant buffer in red blood cells. The major extracellular buffer is bicarbonate. An approximation of the total body buffer capacity is 15 mEq/kg. More than half of the total body alkaline buffer content is located outside the ECF and may in large part reside in bone.⁵⁰ The buffer pair carbonic acid/bicarbonate (H₂CO₃/HCO₃⁻) is the primary buffer system of the body.

From a chemical point of view, the ideal buffer should have a pK_a that allows normal physiologic pH. The H₂CO₃/HCO₃⁻ buffer system has a pK_a of only 6.1, which is not the normal body pH. That said, this buffer system is efficient because of the presence of large amounts of bicarbonate, the conversion of its acid H₂CO₃ to CO₂ that is rapidly excreted through the lungs, and an inexhaustible supply of CO₂ from metabolism.

Acid–Base Disturbances

9 There are four primary acid–base disturbances, each of which are related to changes in either [HCO₃⁻] or PCO₂. These are categorized as metabolic and/or respiratory (Table 11-17). A metabolic acidosis is a decrease in pH as a result of a relative decrease in [HCO₃⁻], whereas a metabolic alkalosis is an increase in pH caused by a relative increase in [HCO₃⁻]. A respiratory acidosis is a decrease in pH secondary to a relative increase in PCO₂, and a respiratory alkalosis is an increase in pH caused by a relative decrease in PCO₂. In each of these disorders, compensatory changes occur to minimize changes in the relative ratio of [HCO₃⁻] to PCO₂ and thereby blunt the effect of the primary disturbance on pH.^{48,49}

Metabolic Acidosis

Anion Gap

The difference in the measured serum cations and anions yields the anion gap. This can be utilized to identify the etiology of a metabolic acidosis. The most common equation used in practice is as follows:

$$\text{Anion gap} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

The normal value of serum anion gap is approximately 3 to 10; however, each laboratory should establish its own normal. If one includes potassium in the equation then the normal value should be increased by about 4 mEq/L. The differential for an elevated anion gap acidosis includes: lactic acidosis, salicylate poisoning, acute or chronic kidney disease, chronic acetaminophen ingestion, ketoacidosis (i.e., diabetic), and acute or chronic kidney disease. A common mnemonic used to address etiologies is the acronym: MUDPILES: methanol, uremia, diabetic ketoacidosis, propylene glycol, isoniazid, lactic acidosis, ethylene glycol, and salicylates.

Mechanisms of Metabolic Acidosis

Four mechanisms result in a decrease in extracellular bicarbonate concentration and metabolic acidosis:

1. Dilutional acidosis. Rapid infusion of an alkali-free solution results in dilution of the bicarbonate concentration.
2. Increased acid generation (e.g., lactic acidosis, ketoacidosis, salicylate poisoning).
3. Diminished renal acid excretion (e.g., renal failure or type I renal tubular acidosis [RTA]).
4. Decreased body bicarbonate content (e.g., severe diarrhea, fistula, type II RTA).

Table 11-18 Compensatory Mechanisms

Disorder	Compensation	Time
Metabolic acidosis	$\text{PCO}_2 = \text{serum HCO}_3^- + 15$ $\text{PCO}_2 = 1.5 \times \text{serum HCO}_3^- + 8 \pm 2$	12–24 hr
Metabolic alkalosis	0.7 mm Hg PCO_2 per 1 mEq/L HCO_3^-	12–24 hr
Acute respiratory alkalosis	2 mEq/L HCO_3^- per 10 mm Hg PCO_2	<3 days
Chronic respiratory alkalosis	4–5 mEq/L HCO_3^- per 10 mm Hg PCO_2	3–5 days
Acute respiratory acidosis	1 mEq/L HCO_3^- per 10 mm Hg PCO_2	<3 days
Chronic respiratory acidosis	–4 mEq/L HCO_3^- per 10 mm Hg PCO_2	3–5 days

The most common example of a dilutional acidosis is large resuscitation with normal saline, which causes a hyperchloremic acidosis. Clinically significant metabolic acidosis in surgical patients is most commonly related to net loss of bicarbonate. One means of classification would be renal acidosis versus extrarenal acidosis. Renal acidosis is not as readily compensated because by definition the kidney's ability to regulate acid/base is compromised. Extrarenal acidosis can be further subdivided into increased acid production (e.g., lactic acidosis in shock) or increase bicarbonate loss (e.g., fistula).

Increased Production of Organic Acids

Increased protein intake and tissue catabolism resulting in greater metabolism of sulfur-containing amino acids can lead to generation of increased amounts of sulfuric acid. With normal kidney function, any decline in serum bicarbonate concentration stimulates renal acid excretion, which can compensate almost completely for the increase in acid production.

Nonrenal Loss of Bicarbonate

Diarrhea, intestinal or pancreatic fistulas, and burns can cause metabolic acidosis secondary to loss of bicarbonate. Urinary diversion with segments of GI tract (ureterosigmoidostomy and ureteroileostomy) can result in loss of bicarbonate with reabsorption of NH_4Cl from the urine. The potential for fistulas to result in metabolic acidosis depends on the concentration of bicarbonate in the fluid and the rate of external drainage. For instance, metabolic acidosis is less common with biliary fistulas than pancreatic fistulas. Biliary fistulas typically have only modest volumes with a bicarbonate concentration of approximately 50 to 60 mEq/L, whereas pancreatic fistulas can have profuse output with a concentration of 150 mEq/L.

Ketoacidosis

Normally, free fatty acids generated from breakdown of triglycerides in adipose tissue are either used as an energy source by tissues such as muscle or carried to the liver, where they are reesterified to triglycerides. Ketoacids are produced by mitochondrial metabolism of free fatty acids to acetyl CoA, with subsequent formation of acetoacetate and β -hydroxybutyrate (redox forms of the same compound). Under normal conditions, a small amount of ketoacid is produced. During prolonged starvation, production of ketoacid increases to modest levels, providing an important source of energy to nonhepatic tissues, particularly the brain. In DKA, the ketoacid production is excessive because of insulin deficiency, which drives ketoacid production by increasing free fatty acid release from adipose tissue, increasing transport of free fatty acids into hepatic mitochondria, promoting conversion of acetyl CoA to ketoacids, and impairing extrahepatic use of ketoacids. Insulin deficiency also contributes to hyperglycemia by decreasing the metabolism of glucose by extrahepatic tissues and increasing hepatic production of glucose. The resulting osmotic glucose diuresis causes increased renal excretion of sodium and water. Additional losses of sodium and potassium occur as a result of renal excretion of the excess ketoacid anions. Potassium excretion is further enhanced by hyperaldosteronism due to increased delivery of sodium to the distal tubule that occurs in association with the osmotic diuresis. Despite total body potassium depletion, serum potassium concentration is often increased in DKA secondary to metabolic acidosis, renal insufficiency, insulin deficiency, and hyperosmolality. These pathophysiologic changes result in the typical clinical presentation, which includes dehydration, polyuria, polydipsia, hyperglycemia, hyperventilation, and metabolic acidosis with an increased anion gap.

Lactic Acidosis

Lactic acidosis can be characterized as type A (caused by tissue hypoxia) or type B (other causes). The generation of lactic acid is the final step of anaerobic glycolysis. Lactic acid is normally produced by muscle, blood elements, intestine, and skin and is used by the liver and kidney. Normal serum lactate concentration is below 2 mEq/L. Lactic acidosis secondary to hypoxia is usually due to increased

production of lactate as well as decreased use, and exists when serum lactate concentration is greater than 6 mEq/L.

The most common cause of type B lactic acidosis is ethanol intoxication. Lactic acidosis is caused by increased generation of NADH by the metabolism of alcohol, which interferes with hepatic gluconeogenesis and, therefore, lactate use.

In lactic acidosis, the L-isomer is usually elevated because of the specificity of mammalian lactate dehydrogenase. Various bacteria found in colonic flora are capable of generating large amounts of D-lactic acid. D-lactic acidosis has been reported in humans only in the presence of short-gut syndrome because the small bowel normally absorbs the dietary substrate for bacterial D-lactic acid production. In addition, the colon must be selectively colonized by bacteria that possess D-lactate dehydrogenase. Typically, the patient has short-gut syndrome, and the acidosis is preceded by food ingestion and is accompanied by characteristic neurologic findings, including mental confusion, slurred speech, staggering gait, and nystagmus. These neurologic manifestations are secondary to bacterial neurotoxins. The acidosis is accompanied by an increased anion gap, but L-lactate and ketone levels are normal. Treatment includes oral antibiotics, recolonization of the colon with non-D-lactate dehydrogenase-forming bacteria, and a low-carbohydrate diet.

Renal Acidosis

The most common renal-associated acidosis in surgical patients is that of acute or chronic renal failure. One of the kidney's many important functions is to excrete acid. When GFR decreases so does the ability to excrete acid, thus causing a metabolic acidosis.

The impaired ability of the kidney to excrete acid may be secondary to a decrease in the number of functioning nephrons and is termed RTA. Type I (distal) RTA is most commonly caused by autoimmune diseases (e.g., Sjogren disease or rheumatoid arthritis) and hypercalciuria in adults. Distal RTA leads to impaired distal acidification.

Type II (proximal) RTA is caused by a reduction in proximal bicarbonate reabsorption – the most common cause in adults being monoclonal gammopathies or medications such as carbonic anhydrase inhibitors.

Clinical Features of Acute Metabolic Acidosis

The major cardiovascular effects of acute metabolic acidosis are peripheral arteriolar dilatation, decreased cardiac contractility, and central venous constriction. These can lead to cardiovascular collapse and pulmonary edema. Catecholamine secretion is stimulated by metabolic acidosis, and in mild cases (pH >7.1), heart rate may be increased. In more severe metabolic acidosis (pH <7.1), the direct effects of acidosis override the catecholamine effects and result in bradycardia and decreased contractility. These depressive effects are magnified by β -blockers. In addition to these cardiovascular effects, metabolic acidosis can increase oxygen delivery by shifting the oxygen-hemoglobin dissociation curve to the right. In more prolonged metabolic acidosis, this may be partially offset by decreased production of 2,3-diphosphoglycerate in red blood cells because of a slower rate of glycolysis. Metabolic acidosis can also cause gastric distention, abdominal pain, nausea, and vomiting.

Algorithm 11-3. Guidelines for the treatment of diabetic ketoacidosis.

Renal Compensation

The kidney is extremely sensitive to changes in serum bicarbonate concentration and responds by increasing net acid excretion primarily in the form of ammonia excretion. Maximal renal compensation requires 2 to 4 days. In addition, the maximal amount of ammonia excreted during acidosis depends on factors such as glutamine delivery, GFR, and the type of anion that accompanies the acid, because renal acid secretion is stimulated to varying degrees by different anions. Although renal compensation is effective in achieving normal net acid excretion with extrarenal causes of metabolic acidosis, variable results are seen with renal acidosis, especially distal RTA.

Respiratory Compensation

A decrease in blood pH causes an immediate stimulus to hyperventilate. Although effective in promptly raising blood pH, early ventilatory compensation is only partial. Full respiratory compensation can occur in 12 to 24 hours. The magnitude of the decrease in PCO_2 in response to a given degree of metabolic acidosis can be used to determine whether the metabolic acidosis is complicated by coexisting respiratory acidosis or respiratory alkalosis. There are multiple equations that can describe this relationship; whichever is easiest remembered can be utilized:

$$\text{Arterial PCO}_2 = \text{Serum HCO}_3^- + 15$$

$$\text{Arterial PCO}_2 = 1.5 \times \text{Serum HCO}_3^- + 8 \pm 2 \text{ (Winter equation)}$$

The PCO_2 can fall no lower than 8 to 12 mm Hg in response to a severe metabolic acidosis and this compensation can only be maintained for a limited period of time due to respiratory muscle fatigue.

Treatment of Acute Metabolic Acidosis

In surgical and trauma patients, metabolic acidosis is often the result of inadequate tissue perfusion and consequent lactic acidosis. Volume resuscitation alone may be enough to correct this acidosis. Attempts to correct acidosis with exogenous bicarbonate without addressing inadequate tissue perfusion will be unsuccessful. Furthermore, exogenous administration of bicarbonate may cause a superimposed respiratory alkalosis and a deleterious left shift of the oxygen–hemoglobin dissociation curve, by not allowing reversal of 2,3-diphosphoglycerate depletion, hence resulting in tissue hypoxia.

Diabetic Ketoacidosis

Initial therapy must include four components: intravenous fluid, insulin, potassium, and the need for bicarbonate. Intravenous fluid should be given in the form of normal saline. On average 4 to 5 L of fluid are required within the first 24 hours. While doing this, serum sodium levels should be monitored. The initial dose of insulin is typically 0.1 unit/kg intravenous or 0.3 unit/kg subcutaneously administered. Insulin should be redosed every 1 hour intravenously or every 2 hours subcutaneously until serum glucose reaches 200 mg/dL. In terms of potassium replacement, it is paramount to ensure adequate renal function (i.e., urine output of at least 0.5 mL/kg/hr). Once adequate urine output is assured, potassium repletion is dosed. If the serum potassium is >5.3 then no further potassium should be given, whereas if serum potassium is 3.5 to 5.3, 20 mEq is added to each liter of fluid. If the serum potassium is <3.5 then 20 mEq/hr of potassium can be administered until serum potassium is in the ideal 3.5 to 5.3 range. Determination for bicarbonate therapy is largely based on pH. If the pH is <7 then it is reasonable to dilute sodium bicarbonate (100 mmol) in 400 mL water and infuse over 2 hours, then rechecking the pH ([Algorithm 11-3](#)).^{51,52}

Metabolic Alkalosis

Sustained metabolic alkalosis occurs only if extracellular bicarbonate concentration is increased and renal excretion of excess bicarbonate is inhibited. Extracellular bicarbonate concentration increases can occur through several mechanisms. In surgical patients, loss of HCl is a frequent cause of metabolic alkalosis, most commonly due to vomiting or nasogastric drainage in the presence of gastric outlet obstruction. External loss of gastric acid results in a net gain in bicarbonate (generated by equimolar gastric secretion of HCl), which causes alkalosis. Although the kidney can excrete excess bicarbonate, this must be accompanied by excretion of sodium. Renal excretion of sodium is limited in the presence of the volume depletion that occurs with external losses of gastric secretion. As volume depletion progresses, sodium is conserved in exchange for hydrogen, and urine will become acidic, even in the presence of severe metabolic alkalosis. This phenomenon is referred to as *paradoxical aciduria*.

Increased extracellular bicarbonate concentration can occur with administration of either bicarbonate or precursors of bicarbonate, such as lactate, citrate, or calcium carbonate, or as a result of increased renal production of bicarbonate. Conditions in which acid excretion exceeds endogenous acid production and in which the renal threshold for bicarbonate reabsorption is increased can result in metabolic alkalosis. Such conditions include moderate potassium depletion, excess mineralocorticoids, and high PCO_2 .

Hypokalemia and cellular exchange of potassium for hydrogen can also lead to metabolic alkalosis. Hypokalemia results in enhanced proximal tubular bicarbonate reabsorption and distal tubular acid excretion. When potassium leaves the cell, it is exchanged for either sodium or hydrogen to maintain electrical neutrality. Loss of potassium from the body then results in a net gain in bicarbonate in the ECF.

Maintenance of elevated extracellular bicarbonate concentration can occur by a number of mechanisms. Volume contraction leads to decrease in renal blood flow and GFR thus reducing the filtered load of bicarbonate. This, in addition to increased proximal tubular reabsorption of bicarbonate, maintains high extracellular concentrations of bicarbonate. High PCO_2 causes an increase in renal threshold for bicarbonate secondary to decreased intracellular pH of the renal tubular cell. The net result is increased bicarbonate reabsorption.

Diuretics can cause or exacerbate metabolic alkalosis by both causing rapid contraction of intravascular volume and increasing renal excretion of acid. Chloride deficiency is another common factor that maintains an alkalotic state. In some instances of metabolic alkalosis, urinary excretion of chloride is markedly reduced. Reversal of metabolic alkalosis in these cases can be readily achieved by administration of chloride-containing solutions. Metabolic alkalosis can be categorically divided into chloride-responsive and chloride-resistant types.

Clinical Features

Clinical signs of metabolic alkalosis may not be prominent because the condition usually develops slowly. If acute, CNS manifestations of confusion, obtundation, stupor, and coma may be present as well as tetany or neuromuscular irritability.

Respiratory Compensation

Respiratory compensation for metabolic alkalosis should raise the PCO_2 by 0.7 mm Hg for every 1 mEq/L elevation in serum HCO_3^- . Typically the arterial PCO_2 does not go above 55 mm Hg. Among the four major acid–base disorders, this compensatory mechanism is the least effective.⁶⁰

Treatment

Correction of the underlying cause is the mainstay of treatment in this disorder. In general, correction of potassium depletion and volume depletion corrects the metabolic alkalosis. Renal excretion of bicarbonate cannot occur in the face of persistent volume depletion. Volume depletion should be corrected with chloride-containing solutions. In patients without intravascular volume deficits, renal excretion of bicarbonate can be enhanced by administration of the diuretic, carbonic anhydrase inhibitor acetazolamide. In extremely rare circumstances where renal excretion of bicarbonate cannot be increased because of underlying renal insufficiency or if the metabolic alkalosis is severe, acid may be administered to titrate in opposition the excess extracellular bicarbonate. Acids that can be used include ammonium chloride, arginine hydrochloride, lysine hydrochloride, or dilute hydrochloric acid (0.1N). Partial correction of the alkalosis is the initial goal and a specialist should be involved prior to instituting this care. In the face of frank renal failure, dialysis may be necessary to remove excess bicarbonate.

Respiratory Alkalosis

Respiratory alkalosis is defined as increased extracellular pH secondary to decreased PCO_2 with hyperventilation. Hyperventilation and the ensuing fall in PCO_2 may be secondary to hypoxia, reflex stimulation from decreased pulmonary compliance, drugs, mechanical ventilation, or other causes.

Hypoxia stimulates ventilation through peripheral chemoreceptors in the carotid and aortic bodies. Decrease in arterial partial pressure of oxygen (pO_2), rather than in oxygen content, is the main stimulus. Acute drops in arterial pO_2 result in sustained hyperventilation only when the PCO_2 decreases below 60 mm Hg. Although hyperventilation occurs with even slight degrees of hypoxia, the resulting

increase in brain pH suppresses the stimulus for hyperventilation unless severe hypoxia is present. In contrast, chronic hypoxia results in hyperventilation even with mildly decreased PCO_2 because brain pH is lowered by metabolic compensation. The two most common causes of hypoxia resulting in respiratory alkalosis are pulmonary disease and exposure to high altitudes.

Clinical Features

Chronic respiratory alkalosis is usually asymptomatic because compensatory mechanisms are successful in maintaining pH close to normal. Acute respiratory alkalosis may cause sensations of breathlessness, dizziness, and nervousness and can result in circumoral and extremity paresthesias, altered levels of consciousness, and tetany. These signs are related to decreased cerebral blood flow secondary to the decreased PCO_2 and decreased ionized calcium concentration secondary to the increased blood pH.

Compensatory Mechanisms

Tissue buffering is the initial response to a decrease in PCO_2 . Red blood cells provide one-third of the buffering. Consumption of bicarbonate results from cellular liberation of H^+ . The magnitude of tissue buffering is weak compared with renal compensation. This is accomplished not by increasing bicarbonate excretion but by decreasing net acid excretion, namely ammonia. Acute compensation is not as strong as chronic compensation, which takes at least 3 days to occur.

Acute compensation: Decrease serum HCO_3^- by 2 mEq/L per 10 mm Hg reduction in PCO_2

Chronic compensation: Decrease serum HCO_3^- by 4 to 5 mEq/L per 10 mm Hg reduction in PCO_2

Treatment

The underlying stimulus for the hyperventilation should be addressed. The cause of hypoxemia should be determined and corrected. In acute symptomatic respiratory alkalosis, rebreathing or breathing 5% CO_2 temporarily relieves symptoms. If the condition is secondary to mechanical ventilation, decreasing tidal volume or respiratory rate should result in resolution of respiratory alkalosis.

Respiratory Acidosis

Respiratory acidosis is defined by a decrease in extracellular pH from a primary increase in PCO_2 , due to inadequate ventilation. Causes of hypoventilation include CNS depression, impaired pulmonary mechanics, airway obstruction, and chronic obstructive pulmonary disease (COPD). In addition, inappropriate ventilator settings may result in respiratory acidosis in patients on mechanical ventilation.

Clinical Features

The magnitude of clinical manifestations depends on the chronicity and rate of development of respiratory acidosis. Acute increases result in cerebral acidosis, manifested by drowsiness, restlessness, and tremor, as well as stupor or coma in more severe cases. Cerebral vasodilation occurs in response to acidosis, resulting in increased cerebral blood flow. This may, in turn, result in increased intracranial blood pressure, headache, and papilledema. Systemic acidosis results in peripheral vasodilatation, depressed cardiac contractility, and insensitivity to catecholamines.

Figure 11-8. Acid–base nomogram. Shown are the 95% confidence limits of the normal respiratory and metabolic compensations for primary acid–base disturbances. (Reproduced with permission from Cogan MG, Rector FC Jr. Acid–base disturbances. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:473.)

Compensatory Mechanisms

Increased pCO_2 results in increased H_2CO_3 , which dissociates into H^+ and HCO_3^- . Cellular exchange of Na^+ and K^+ for H^+ allows the reaction to continue in this direction with increased extracellular bicarbonate. This tissue buffering is accomplished within minutes. Persistently elevated PCO_2 also stimulates increased renal acid excretion, primarily the chloride salt of ammonia, and results in increased renal generation of HCO_3^- . Full renal compensation occurs over 3 to 5 days.

Acute compensation: 1 mEq/L HCO_3^- per 10 mm Hg PCO_2

Chronic compensation ~ 4 mEq/L for every 10 mm Hg PCO_2

Treatment

Treatment should be directed to the underlying cause of hypoventilation. Endotracheal intubation to achieve adequate ventilation is paramount to the treatment of acute respiratory acidosis of any cause. In select cases of respiratory acidosis, namely patients with COPD, noninvasive positive pressure ventilation (i.e., CPAP/BiPAP) has proven effective. However, patients must be able to protect their airway and have no major concern for aspiration (i.e., not appropriate in the setting of a bowel obstruction). Furthermore, there must be close follow-up to ensure the acidosis is resolving.

The treatment of chronic, compensated respiratory acidosis may be complicated by the accompanying hypoxemia. In chronic hypercapnia, the central chemoreceptors may be insensitive, and the accompanying hypoxemia may supply the main respiratory drive through stimulation of peripheral chemoreceptors. In such patients, complete correction of the hypoxemia may further suppress respiration and worsen the respiratory acidosis. In addition, PCO_2 should not be normalized rapidly. Equilibration of cerebral bicarbonate concentration lags behind systemic changes. Thus, even if PCO_2 is normal, cellular and cerebral metabolic alkalosis may develop.

Mixed Acid–Base Disorders

Combinations of two or more of the four primary acid–base disorders may occur and should be suspected when blood pH approaches normal despite abnormal PCO_2 and $[\text{HCO}_3^-]$, or when compensatory changes appear to be either excessive or inadequate (Fig. 11-8). Familiarity with the acid–base disorders associated with various clinical situations and the expectation of mixed abnormalities allows appropriate interpretation of arterial blood gases and serum electrolyte determinations.

Chapter 12

Burns

Benjamin Levi, Mark R. Hemmila, and Stewart C. Wang

Key Points

- 1 Burn reconstruction remains a challenge given the increased survival of burn patients.
 - 2 Most chemical injuries should be treated with dilution of the chemical rather than neutralization.
 - 3 Frostbite outcomes are improved if patients with threatened extremities are treated with tPA within 24 hours of injury.
 - 4 Resuscitation is of crucial importance for burn patient outcome and physicians must be aware when to begin resuscitation ($>20\%$ TBSA) and to monitor the patient's response to avoid overresuscitation.
 - 5 Early excision and grafting within 72 hours of the injury remains a pillar of burn care.
 - 6 Order of burn coverage can affect patient outcome and can help prevent the patient from needing a tracheostomy.
 - 7 In addition to surgical treatment of hypertrophic scars, new laser technologies allow for scar rehabilitation improving the quality and pain associated with these scars.
-

INTRODUCTION

Burn injuries represent a major source of trauma, subsequent scarring and debility throughout the world. Improved worker safety programs, fire prevention efforts, and fire detection systems have significantly decreased the prevalence of major burn injuries. Burn patients have also benefited from recent improvements in surgical critical care in areas such as lung protective ventilation, blood glucose control, and antibiotic stewardship. Overall, survival after burn injuries remains high, leading to a large need for improved reconstructive treatment options for burn scar rehabilitation.

EPIDEMIOLOGY

1 Based on the American Burn Association (ABA) National Burn Repository, 450,000 people receive medical treatment for burns annually. There are 40,000 hospital admissions and 3,400 deaths per year from fire and smoke inhalation.¹ Of these patients, 69% are male, 59% are Caucasian, 20% are African American, and 15% are Hispanic. The cause of these burn injuries varies with 43% from fire or flame burns, 34% from scald burns, 9% from contact burns, and 7% are electrical and chemical burns. With increased safety emphasis in the workplace, only 9% of these injuries occur at work. The majority of chemical, electrical, and molten burns occur at home and 72% of all burn injuries happen at home. As in other trauma populations, children are affected to a greater degree. Children under 8 years of age typically suffer from scald burns caused by spilling of hot liquids. With improved surgical critical care and understanding of burn injury physiology, over 96% of burn patients survive. Thus, with improved treatments and survival, there has also been an increased focus on burn reconstruction and scar management.

Children

Infants and children up to 4 years old comprise almost one-third of burns. Burns are the fifth leading cause of unintentional nonfatal injury in infants and the third leading cause of fatal injury for newborns to children 9 years of age. Scald burns caused by hot liquids are the most common cause of pediatric burns and occur most often in the home.²⁻⁵ The number of burns decreases from age 9 until adolescence and increases again after the age of 15, presumably due to greater exposure to hazards,

experimentation, risk-taking, and employment.⁶ Intentional burns account for around 10% of all cases of child abuse.⁷ Scalds from hot bath immersion are the most frequent cause of these cases. Other common etiologies of intentional burns include contact with heated objects including cigarettes, irons, and heated kitchen utensils.

Adults

In contrast to the pediatric population, flame burns are the most common cause of burns in adults and the elderly. Flame burns account for 35% to 42% of hospital admissions in adults, while scald burns account for 15% to 18% of hospital admissions related to burn injuries.³ Cigarette ignition of upholstered furniture or bedding accounts for 47% of fires and alcohol appears to be a significant contributor.⁸

Elderly

The elderly (defined by age greater than 65 years) suffer a disproportionately higher percentage of hospitalizations due to burns in comparison to the general adult population. A 10-year analysis from 1995 to 2005 using data from the National Burn Repository showed that individuals over the age of 65 comprised 12% of all burn unit admissions and that the average age of those admitted was 76 ± 7 years.⁹ The most frequent cause of burns that led to death in elderly women was a result of clothing ignition during cooking.¹⁰ Elderly burn patients treated for scald burns had relatively small burns ($<13\%$ of total body surface area [TBSA]) but high mortality rates (30%).^{11–13} Overall, burns are the fourth leading cause of mortality in the elderly population. Together, these results suggest that the medical, economic, and social burdens of burn will likely increase as the general population continues to age.

Race and Ethnicity

Differences also exist in the susceptibility to burns by race and ethnicity. Burns are the leading cause of injury-related death in Black children between the ages of 1 and 9 and the rates are 2.7 times higher than in White, Hispanic, and Asian/Pacific Islander children.¹⁴ Likewise, in adults, the rate of nonfatal burns in Black Americans aged 35 to 39 years was 221 per 100,000 Blacks, which is remarkably higher than the 135 per 100,000 Whites with burns in the same age group.³ The emergency room visit rate for burns from 1993 to 2004 in the United States was 62% greater among Black Americans (340 per 100,000 Black Americans) than White Americans (210 per 100,000 White Americans).¹⁵ The age-adjusted death rate from burns of all causes in the United States in 2006 was highest in Blacks (2.4 per 100,000) and lowest in Asians (0.4 per 100,000), with Native Americans (1.5 per 100,000), White non-Hispanics (1.1 per 100,000), and Hispanics (0.8 per 100,000) falling in between this range.³ These trends can be translated to the elderly population, as the mortality rate for burn-related injuries in the elderly was 4.6 times greater in Black Americans than in White Americans.¹⁶

There are also significant differences in the gender distribution of burns between age groups. Adult men more frequently seek care in the emergency department (69%). This may be due to the increased severity of their burns caused by industrial accidents, compared to women (31%).⁶ Elderly are also more highly represented among older burn victims than in younger populations.^{17,18} The greater preponderance of older women with burn injuries reflects the decrease in workplace-related injuries among the geriatric population.

Socioeconomic Status

Socioeconomic status (SES) factors such as low household income, crowded household living conditions, and unemployment also increase the risk of burns. In the metropolitan Oklahoma City, Oklahoma, the overall fire-related hospitalization and death rate was 3.6 per 100,000.¹⁹ Stratification of the data based on household income, property values, and quality of housing demonstrated that the injury rate in lower SES was 15.3 per 100,000.²⁰ The proportion of children in the lowest SES groups requiring hospitalization for treatment in US burn centers is twice the proportion of all children in the general population.³ Furthermore, the incidence of house fires was eight times greater in low income families compared to high incomes.²¹ The higher incidence of house fires has been attributed to the frequent absence of functioning smoke detectors.²¹ Together, these results highlight the increased need for education and prevention campaigns for lower SES groups to reduce household fires and burn injuries.

ETIOLOGY

Numerous modalities, including fire or flame, scalds, contact, electrical conduction, and chemicals can produce burns. Between 2002 and 2011, 44% of burns were produced by fire or flame, 33% by scald, 9% by contact, 4% by electricity, 3% by chemical, and 7% defined as other.

Burns are caused by contact of heat, cold, or chemicals with the cutaneous surface of the skin. The depth of the burn injury is proportional to the temperature and duration of exposure. Burn depth is also dependent on the body region due to differences in skin thickness and blood flow.

Scald burns are most commonly caused by water in the community. Once the water temperature exceeds 156°F, only 1 second is needed for a full-thickness burn injury. The difference in contact time underlines the importance of making sure hot water heaters are set at a low enough temperature to minimize childhood bath and shower scald injuries (120°F). It takes 3 minutes for a burn to occur from 120°F whereas it takes only 1 second for a burn to occur from 156°F water.

Though water scalds do not always cause full-thickness injury due to the variation in temperature, grease burns almost uniformly cause a deep partial- or full-thickness burn. Grease is usually 400°F and thus even minimal exposure will cause significant thermal injury. Tar and asphalt also exceed 400°F to 500°F making them a high burn injury risk for industrial workers. Water and grease injury sites should be cleansed with aqueous solutions. Tar, however, requires a petroleum-based solution to remove it from the burn wound.

Flame Burns

Thermal injuries, caused by fire or flames, are the most common burn etiology reported over the past decade.²² These injuries usually occur as a result of flammable liquids, motor vehicle crashes, cooking fires, or if bedding/clothes ignite. Despite improved fire safety at home with smoke detectors as well as improved safety at industrial sites, flame injuries are still relatively common and frequently cause partial- and full-thickness burn injuries. Flame injuries are associated with the highest risk of death and complications compared to all other burn etiologies. Flame burns most commonly occur at home (64%), while work fires and recreational fire burns account for 12% and 6% of flame burns, respectively. When evaluating thermal injuries, it is important to consider the possibility of smoke inhalation as its presence significantly impacts the morbidity and mortality of patients with flame burns. Inhalation injury occurs in 17% of patients with flame burns. The presence of smoke inhalation in burn patients is associated with an overall mortality rate of 24%, compared to the mortality rate of 4% in patients without smoke inhalation.

Contact Injuries

Contact burns occur as the result of direct contact with hot surfaces and material, most frequently glass, metal, or plastic. The depth of the injury will depend on the heat of the material and the length of contact. Frequent sites of injury include the palms of the hands as people, especially toddlers, often fall with outstretched hands. Other commonly seen contact injuries are due to hot metal devices such as space heaters, curling irons, or motorcycle exhaust systems.

Electrical Burns

Electrical injuries occur more frequently in adults than children since most result from occupational exposure. As one of the most devastating and debilitating injuries cared for in burn centers, electrical injuries comprise 4% of all reported etiologies. Patients who have high-voltage electrical injuries, defined as greater than 1,000 V, are at elevated risk of spine fracture injury due to tetany and require complete immobilization until vertebral injury is excluded. Providers must also evaluate patients with high-voltage injuries for cardiac damage. Direct muscle injury from current flow may cause gross myoglobinuria, requiring more aggressive fluid resuscitation.²³ Patients with gross myoglobinuria often require fasciotomy of affected limbs and a severe electrical injury often requires monitoring in the ICU. Bone has the highest conductance and electricity flows along the skeleton cause significant muscle necrosis adjacent to the bone. TBSA involved is not necessarily associated with prognosis and it does not quantify damage to deep tissues in electrical injuries.

Thermal injuries occur as electricity can generate temperatures over 100°C. Electroporation occurs as electrical force drives water into lipid membrane causing cell rupture. Tissue resistance in decreasing order includes bone, fat, tendon, skin, muscle, vessel, and nerve. Bone heats to a high temperature and burns surrounding structures such as muscle which is the reason why muscle swelling and compartment

syndrome are common in high-voltage electrical injuries.

Alternating current causes tetanic muscle contraction and the “no let-go” phenomenon. This occurs due to simultaneous contraction of (stronger) forearm flexors and (weaker) forearm extensors. Current flow through tissue can cause burns at entrance/exit wounds and hidden injury to deep tissues. Current will preferentially travel along low-resistance pathways. Current will pass through soft tissue, contact high-resistance bone, and travel along bone until it exits to the ground. Vascular injury to nutrient arteries and damage to intima and media can result in thrombosis.

Electrical exposure can cause significant injuries to other organ systems besides the skin and musculoskeletal system. From a cardiac standpoint, arrhythmias are common at the scene (any voltage) or in the hospital (high voltage $\geq 1,000$). Heart rhythm should be monitored continuously for at least 24 hours if cardiac injury is suspected at the scene or if a high-voltage injury has occurred. Ventricular fibrillation and asystole are the most common and Advanced Cardiac Life Support should be instituted immediately. Coronary artery spasm and myocardial injury and infarction have also been described. A normal cardiac rhythm on admission, however, means dysrhythmia is unlikely and thus 24-hour monitoring is not needed.²⁴ Additionally, injury to solid organs, acute bowel perforation, and gallstones after myoglobinuria have been described. Myoglobinuria occurs due to the disruption of muscle cells. Myoglobinuria from other causes requires increased fluid administration, however, burn resuscitation usually provides adequate fluid. Cataracts are also a long-term adverse effect of electrical injury necessitating ophthalmology evaluation and follow-up.

When taking the patient to the operating room for debridement and grafting of electrical injuries, the physician should perform serial debridements and allow the tissue to completely declare itself. These injuries will often evolve with progressive muscle necrosis over time, thus early grafting (within the first week) often fails to fully close the burn wound. These injuries have similarities to crush injuries and thus multiple trips to the operating room for debridement should not be viewed as failure.

Chemical Burns

General Approach to Chemical Burn Treatment

2 Healthcare providers should use personal protective equipment – always considering that the chemicals are still present and must be neutralized or temporized. With few exceptions (see below), all chemical burns should be copiously irrigated with water. Water dilutes but does not neutralize the chemical and cools the injured area. Neutralization of the chemical is generally contraindicated because neutralization may induce a hyperthermic reaction leading to further thermal injuries. Water irrigation, however, is contraindicated or ineffective following exposure to elemental sodium, potassium, and lithium (precipitates an explosion). Dry lime should be brushed off, not irrigated. Phenol is water insoluble and should be wiped from the skin with polyethylene glycol-soaked sponges.

Types of Chemical Burns

Alkali causes liquefaction necrosis and protein denaturation and is found in oven and drain cleaning products, fertilizers, and industrial cleaners. Alkali injuries extend deeper into tissues following exposure and are especially disruptive to the eye. **Acids** cause damage tissue via coagulation necrosis and protein precipitation. Acid burns tend to be self-limited secondary to pain as the patient will quickly react to the offending agent. **Organic compounds** (phenol and petroleum) cause damage due to fat solvent action (cell membrane solvent action) and systematic absorption with toxic effects on the liver and kidneys. These agents can also cause significant erythema in the surrounding areas that can be mistaken for cellulitis.

Specific Types of Chemical Burns

Hydrofluoric acid is a potent and corrosive acid used for rust removal, glass etching, and to clean semiconductors. It is a weak acid but the fluoride ion is toxic as it leaches calcium from cells. Hydrofluoric acid causes severe pain and local necrosis and should be treated with copious water irrigation. The fluoride ion is neutralized with topical calcium gel (one ampule of calcium gluconate in 100-g lubricating jelly). If symptoms persist intra-arterial calcium infusion (10-mL calcium gluconate diluted in 80 mL of saline, infused over 4 hours) and/or subeschar injection of dilute (10%) calcium gluconate solution should be administered. Fluoride ion binds free serum calcium and thus it is crucial to make sure to check the serum calcium and replace with intravenous (IV) calcium as needed.

Phenol is commonly used in disinfectants and chemical solvents, it is an acidic alcohol with poor water solubility. Phenol causes protein disruption and denaturation resulting in coagulation necrosis.

Systemically, phenol can cause cardiac arrhythmias and liver toxicity. Thus patients should have cardiac and liver functions monitored. Additional adverse effects include renal injury and demyelination. Given phenol's anesthetic effect, pain is not a reliable indicator of injury. Treatment is copious water irrigation and cleansing with 30% polyethylene glycol or ethyl alcohol.

Tar is used in the paving and roofing industry and can be heated to 260°C (~500°F) prior to application. Tar causes thermal injury and then solidifies as it cools, often becoming enmeshed with hair and skin. Patients with tar injuries should be cooled with copious water irrigation to stop the burning process. Tar removers promote micelle formation to break the tar – skin bond. Sterile surfactant mixture (De-Solv-it or Shur-Clens) allows tar to be wiped away quickly. Wet dressings using polysorbate (Tween 80) or Neomycin cream for 6 hours prior to tar removal can also be effective.

White phosphorus is used to manufacture military explosives, fireworks, and methamphetamine. Obvious particles should be brushed off. Skin should be irrigated with 1% to 3% copper sulfate solution. Copper sulfate stains the particles black for identification. Copper sulfate will also prevent ignition when particles are submerged in water. After copper sulfate irrigation, the exposed area should be placed in a water bath and the white phosphorous removed.

Anhydrous ammonia is an alkali used in fertilizer. Skin exposure is treated with irrigation and local wound care. Exposure is associated with rapid airway edema, pulmonary edema, and pneumonia. It is important to consider early intubation for airway protection in these cases.

Methamphetamine injuries have been on the rise. In addition to these compounds being highly flammable, exposure to methamphetamines causes tachycardia (greater than expected with a similar size burn), hyperthermia, agitation, and paranoia. Any suspicion of chemical injury to the globe should be treated with prolonged irrigation with Morgan lenses. Eyelids may need to be forced open due to edema or spasm. Utilize topical ophthalmic analgesic and consult an ophthalmologist.

Frostbite

Frostbite injuries frequently result in severe ischemic damage of distal extremities. Frostbite classification is similar to that of burn injury with first degree demonstrating hyperemia and no blisters with no tissue loss expected; second degree having blisters and edema but still no tissue loss; third degree with hemorrhagic blisters, throbbing pain, and likely tissue loss; and fourth degree with mottled or cyanotic skin, hemorrhagic blisters, and frozen deeper tissues.

3 Historically, these patients have been managed expectantly with long periods of observation followed by amputation of devitalized tissue. Recent advances with interventional radiology, thrombolytic therapy, and nuclear medicine have changed the treatment paradigm and protocol for these patients ([Algorithm 12-1](#)). Current treatment paradigms for patients with frostbite include rapid rewarming of affected area in 104°F to 108°F water bath, not radiant heat as well as ibuprofen 400 mg, elevation of the limb, tetanus prophylaxis, and appropriate referral. If the patient has severe frostbite within the last 24 hours, the patient should be transferred to a center with interventional radiology expertise. Once they arrive, these patients should receive an arterial line (usually brachial or femoral) and intra-arterial tPA which treat the microvascular thrombosis.²⁵ Additionally, patients might benefit from nitroglycerin to treat vasospasm. Patients should return to the interventional radiology suite after 12 hours to evaluate progress and potentially treat again. In general, tPA is stopped after 48 hours. After 5 to 7 days, a nuclear bone scan can help assess the extent of deeper tissue necrosis as the more superficial tissue will often appear worse than the actual extent of the injury.

Algorithm 12-1

Algorithm 12-1. Protocol for frostbite injury.

PHYSIOLOGY OF BURNS

Burn Shock

Most patients with large burn or inhalation injuries will meet criteria for systemic inflammatory response syndrome (SIRS) (body temperature less than 36°C [96.8°F] or greater than 38°C [100.4°F], heart rate greater than 90 beats per minute, tachypnea greater than 20 breaths per minute, arterial partial pressure of carbon dioxide less than 4.3 kPa [32 mm Hg], blood leukocyte count less than 4,000 cells/mm³, or greater than 12,000 cells/mm³); or the presence of greater than 10% immature neutrophils (band forms). SIRS with infection is defined as sepsis and sepsis in addition to hypoperfusion is defined as “septic shock.” Burn shock does not equate to septic shock in the acute setting as true sepsis from a burn injury with subsequent infection usually does not occur until after the first 48 to 72 hours.

Burn shock is unique in the degree of vascular permeability coupled with increased hydrostatic pressure.²⁶ This increased permeability is thought to result from the release of histamine from mast cells in burned skin following burn injury.²⁷ Histamine interferes with the venous tight junctions and thereby allows efflux of fluid and proteins causing intravascular hypovolemia despite total volume hypervolemia.

Platelet activation products such as eicosanoids and serotonin also act to increase pulmonary vascular resistance and amplification of the vasoconstrictive effects of norepinephrine and angiotensin II.²⁸ In addition to the increased vascular leak, platelet-activating factor and clotting factor dysregulation creates a hypercoagulable state with bleeding that resembles disseminated intravascular coagulation. This coagulation disorder is further amplified if patients become hypothermic during their resuscitation.²⁹ Thus, patient temperature monitoring and maintenance is crucial during resuscitation.

Arachidonic acid metabolism products such as eicosanoids also play a role in burn edema. Eicosanoids increase prostaglandins such as PGE₂ and prostacyclin which cause arterial dilation and increased blood

flow and hydrostatic pressure in regions of injury resulting in increased edema.

Changes in cardiac output are also seen acutely in burn patients as these patients often have an increase in heart rate, and systemic vascular resistance but hypovolemia. Though not defined as “cardiogenic shock,” cardiac function is altered due to inflammatory mediators.³⁰⁻³³ With appropriate burn resuscitation, cardiac output should return to normal levels within 24 to 72 hours.

Metabolic Response to Burn Injury

Hypermetabolism is a physiologic response unique to burn injury. Hypermetabolism is characterized by increased body temperature, glycolysis, gluconeogenesis, proteolysis, lipolysis, and prolonged substrate cycling.^{34,35} The degree of the hypermetabolic response is proportional to the size of burn injury and appears to plateau at 70% TBSA. Overall the basal level of glucose is elevated despite a high insulin state which can complicate outcomes and exacerbate muscle catabolism.

Lipolysis also occurs at a rate that is higher than normal due to abnormal substrate cycling. This results in hepatic accumulation of triglycerides causing steatosis. Recent work to combat peripheral lipolysis has had some success using propranolol.³⁶

Proteolysis is also increased in burn patients compared to nonburn patients. This is due to a combination of increased muscle breakdown and increased plasma protein production by the liver. Wound healing requires an increase in protein synthesis leading to the recommendation of enteral nutrition with elevated protein levels.

There are three ways to influence hypermetabolism: nutrition, medication, and surgery. Current protocols preferentially recommend continuous enteral nutrition with a high-carbohydrate diet consisting of 82% carbohydrate, 3% fat, and 15% protein. This diet is thought to stimulate protein synthesis, increase endogenous insulin production, and improve overall lean body mass when compared to standard formulas.³⁵

Catecholamines are significantly elevated following a burn injury and are thought to play a role in the hypermetabolic response. This elevation is one reason why propranolol administration is thought to be helpful. Interestingly, growth hormone levels have been shown to be decreased in burn shock leading clinicians to supplement patients with the anabolic steroid oxandrolone in large burn injuries. Positive results to avoid or reduce the loss of muscle mass with oxandrolone have made its use standard in most burn units for large TBSA burn patients.³⁷⁻⁴⁴ With regard to thyroid hormone, total thyronine and thyroxin (T3 and T4) are reduced whereas reverse T3 is elevated. Burn injuries also cause alterations in diurnal glucocorticoid levels leading to persistent hypercortisolemia.

Surgery represents the last way to combat hypermetabolism as early debridement and grafting is the mainstay to mitigate the hypermetabolic syndrome.

Immunologic Response to Burn Injury

The immune system in burn patients demonstrates significant dysregulation that may explain increased risk of infection. Serum levels of IgA, IgG, and IgM are decreased indicating decreased B-cell function. T-cell function or cell-mediated immunity is also impaired which is why prolonged homograft and xenograft take is seen. Interleukin 2 (IL-2) production is also decreased whereas IL-10 is increased. Similar to other types of nonthermal trauma, burn patients also have elevated tumor necrosis factor alpha and IL-6. Polymorphonuclear neutrophils have impaired chemotaxis as well as decreased oxygen consumption and impaired bactericidal capabilities.

EMERGENCY CARE

Initial care in the field and emergency room is similar to that of any trauma patient. The airway should be stabilized, IV access should be obtained, concomitant life-threatening injuries should be excluded, and escharotomies should be performed if there are any circumferential areas of full-thickness injury. Escharotomies should be placed on the lateral aspects of the extremities avoiding the sites of potential nerve and large vessel injury (Fig. 12-1). Escharotomies should be extended across the chest if there is full-thickness injuries and if difficult ventilation arises. Abdominal escharotomies can also help with ventilation.

Figure 12-1. Incision lines for escharotomies. In general incisions should be kept on the lateral aspect of extremities to avoid damage to neurovascular structures. (From Holzman RS, Mancuso TJ, Polaner DM, eds. *A Practical Approach to Pediatric Anesthesia*, 2e. Philadelphia, PA: Wolters Kluwer; 2016.)

Table 12-1 Burn Center Referral Criteria⁴⁵

Though patients often present to the nearest emergency room or urgent care center, certain patients have been shown to benefit from transfer to a designated burn center. The American Burn Association has put out a list of criteria for those patients who should be transferred. This includes: 1. Over 10% total body surface area (TBSA) partial- or full-thickness burns 2. Burns that involve difficult anatomic sites such as the face, hands, feet, genitalia, perineum, or major joints 3. Full-thickness burns in any age group 4. Electrical burns, including lightning injury 5. Chemical burns 6. Inhalation injury 7. Burn injury in patients with pre-existing medical conditions that could complicate management, prolong recovery, or affect mortality 8. Any patient with burns and concomitant trauma. If, however, the coincident trauma is of greater risk to mortality, the patient should be stabilized prior to transfer. Physician judgment will be necessary and should be in concert with the regional medical control plan and triage protocols 9. Burned children in hospitals without qualified personnel or equipment for the care of children 10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention

Guidelines from the American College of Surgeons Advanced Trauma Life Support and the ABA Advanced Burn Life Support programs have standardized the care of trauma patients and have improved overall patient outcomes. A complete history and physical should be performed with specific focus placed on the cause and timing of the injury, risk of smoke inhalation injury, concomitant injuries, and

treatments including IV fluids received prior to patient arrival. The primary goal is to stabilize the patient, ensure standard injury assessment, and transfer to a burn center as necessary. The ABA has published criteria to follow regarding when to transfer a patient to a verified burn center ([Table 12-1](#)).

Airway Assessment

Primary survey assessment should begin with evaluation of the airway. Inhalation injuries occur in approximately 10% of all burn patients, but are present in 70% of those who eventually die of their burn injury.⁴⁶ Thus, it is important to specifically note such findings as soon as the patient presents. Risk for inhalation injury can be first assessed by the history. In general, patients burned outside (not in an enclosed space) very rarely suffer inhalational injuries. If, however, the patient was in a burning home or a burning building, one's suspicions should be raised. Close physical examination should note facial burns, changes in voice, shortness of breath, singed nasal vibrissae, carbonaceous sputum, and intraoral swelling. If these findings are present and the patient appears to be in distress, oral intubation should be performed immediately by an experienced airway physician. In addition to a laryngoscope, the trauma team should have a video laryngoscope available and a surgeon present in case a surgical airway is required. If the patient is not in extremis and the level of inhalation injury is unknown, nasoendoscopy or bronchoscopy should be performed to directly visualize the airway and vocal cords. If significant swelling exists and the patient is expected to receive large volume IV fluid resuscitation, the airway should be immediately secured. If a patient is transferred with an endotracheal tube that the accepting physician feels is no longer needed, a spontaneous breathing trial should be performed followed by direct laryngoscopy to assess for cord swelling and assessment for a cuff leak should be performed before removing the endotracheal tube.

Oxygenation in a burned patient may be altered by carbon monoxide (CO) poisoning. Physical examination findings include red lips and altered mental status. Formal diagnosis should be based on history and evidence of CO levels in the blood. CO binding is assessed by measuring the level of carboxyhemoglobin in a peripheral arterial blood gas sample. Symptoms of CO poisoning typically begin with headaches at levels around 10%, while CO in the blood becomes lethal at around 50% to 70%. The half-life of CO is normally 4 hours when breathing room air, however, half-life is shortened considerably with administration of supplemental oxygen. Treatment with 100% oxygen (FiO₂ 100%) reduces the half-life of CO to 30 to 90 minutes. Hyperbaric oxygen treatment can reduce the half-life of CO to 15 to 23 minutes. However, if the patient has additional burn injuries or is unstable, the patient should not be placed in a hyperbaric chamber. Also, the time needed to transfer patients to hyperbaric facilities and the subsequent difficulty of resuscitating a critically ill patient in a closed chamber make hyperbaric oxygen an impractical option. Prompt and aggressive evaluation and maintenance of the airway is the most important initial step in management of a burn patient.

Fluid Resuscitation

It is important to have large bore IV access with 16- or 18G peripheral IVs. IV access catheters should preferentially be placed in nonburned areas of skin although this is not always possible. If the patient will require invasive hemodynamic monitoring, a central line should be placed under sterile conditions. Peripherally inserted central catheter (PICC) lines can be used in burn patients, however, their infection rate remains high. If a central line is used, this does not need to be changed out at a certain timepoint but rather should be monitored daily for signs of infection. Ideally, burn and critical care surgeons would have access to a minimally invasive monitor of cardiac output. Though several technologies exist including esophageal Dopplers, arterial waveform monitors, and thermodilution modalities, the trend of these values is more useful than the absolute values. If a PiCCO device (Pulsion Medical Systems AG, Munich, Germany) is used to monitor the patient, it is best to have the central venous line located in the internal jugular vein and the arterial line in the femoral artery. This technology uses thermodilution to determine cardiac performance. Studies have demonstrated efficacy of this technology when compared to use of a pulmonary artery catheter.⁴⁷ Burn injury and soft tissue edema make noninvasive blood pressure measurement difficult and inaccurate, hence arterial line placement is frequently necessary.

The Parkland or Consensus formula is most commonly used to estimate fluid requirements for the first 24 hours and should be used to guide initial fluid infusion rates. This is a start point and should not be construed as a dogmatic prescription of the total fluid volume to be given during the first day after injury.⁴⁸ It is extremely important to note that the original time of the injury is used in the calculation, not the time of initial presentation to care providers. Partial- and full-thickness burns are totaled to calculate burned TBSA.

Consensus formula: First 24-hour requirement = $2-4 \text{ cc} \times \% \text{TBSA} \times \text{weight (kg)}$

Half of this fluid volume is planned to be administered in the first 8 hours after burn injury and the second half is administered over the next 16 hours. For example, if a 70-kg patient with 20% TBSA burn sustained at 10 AM presents 2 hours later, the crystalloid fluid to be administered in the first 8 hours is calculated using the following formula: $([4 \text{ cc} \times 20\% \times 70 \text{ kg}]/2)/6 \text{ hours}$. Lactated Ringers crystalloid solution is recommended as the first choice fluid to avoid complications associated with metabolic acidosis.⁴⁸ Currently data do not support hypertonic saline, dextran, or albumin during the first 24 hours of resuscitation in standard clinical situations.^{49,50} Studies have suggested that limited albumin usage may play a role in reducing the rate of abdominal compartment syndrome when the patient requires substantially more fluid administration than estimated by the Parkland formula (>1.5 times).⁵¹ Additionally, D5/LR is commonly used for maintenance of fluid in children under 1 year of age to avoid hypoglycemia. Once the Parkland formula is begun, the patient's vital signs and urine output should be closely monitored and laboratory studies should be drawn frequently. Although such formulas exist, it is important to note that proper fluid resuscitation should be guided by overall clinical response and the trend of vital signs and laboratory values. IV fluid infusion rate should be increased or decreased based on the response of the patient on an hourly basis with fluid administration titrated to maintain urine output goals of 0.5 to 1 mL/kg/hr in adults and 1 to 1.5 mL/kg/hr in children. Blood pressure and heart rate should be monitored; burn patients are often tachycardic regardless of the degree of resuscitation. Though urine output is considered a "gold standard," it often lags the fluid status and thus clinicians must be cautious not to reflexively increase fluids with low urine output but rather consider the entire clinical picture. In addition, close monitoring of the patient's laboratories is necessary to determine the trend in organ perfusion. Laboratory values that help assess organ perfusion include lactate, base deficit, central venous O_2 , and/or pH. Although any one of these values alone does not provide a sensitive marker of the patient status, trending these values during resuscitation can help direct resuscitation adjustments if the current fluid rate is causing a positive trend. If the end organs are adequately perfused, decrease in lactate and base deficit as well as increase in central venous O_2 and normalization of pH should be observed.

In the second 24 hours, all patients should receive crystalloid sufficient to maintain urine output and to maintain parameters of perfusion including lactate, pulse volume variation, and cardiac output. Infusion rate will often be at a maintenance rate plus adjustment for losses of fluid into the burn wound. Nutritional support should be started enterally within 24 hours. After 24 to 36 hours, providers can cut fluids by 1/3 if the patient continues to make adequate urine. One may decrease fluids again by 1/3 for hours 36 to 48 (assuming urine output does not drop off). Colloid can be given after initial crystalloid resuscitation (5% albumin at 0.3 to 0.5 mL/kg per %TBSA over 24 hours).

After 48 hours, fluid infusion rate should maintain urine output at 0.5 to 1 mL/kg body weight per hour. Insensible losses and hyperthermia are associated with hyperdynamic states and increase fluid requirements. Daily patient weights can be helpful to determine insensible fluid loss or retention.

Pediatric fluid resuscitation does have some differences with regard to fluid management. Due to the limited reserve in children under 20 kg, a glucose-based maintenance fluid is recommended. Additionally, fluid requirements may be as high as 6 mL/kg per TBSA and their urine output should be 1.0 to 1.5 mL/kg/hr.⁵² Since burn resuscitation should be considered in the setting of a 10% TBSA in children, transfer to a burn center is recommended.

Pulmonary status is also an indicator of fluid status but in a delayed fashion. Complications such as pulmonary edema result from fluid overload and necessitate daily evaluation of oxygen requirements and ventilator settings.

Difficult to Resuscitate Patients

If the fluid resuscitation required during the first 24 hours is 1.5 times greater than initially estimated, the physician should reassess the clinical picture. Giving excessive crystalloid fluids and failure to use appropriate early resuscitation adjuncts are associated with significantly worse outcomes. Physicians often will give additional fluid due to low urine output not realizing that the kidney, like other organs during burn shock, often lags behind the clinical picture. Specific complications associated with excessive resuscitation include compartment syndrome of both the extremities and the abdomen. Signs of abdominal compartment syndrome include abdominal distention, decreased urine output, elevated ventilator pressures, and desaturation. Surgeons should have a low threshold to assess for this devastating complication in any patient requiring resuscitation above the Parkland formula. Diagnosis

can be made both by observing clinical signs as well as by assessment of bladder pressure transduced through a Foley catheter. Pressures over 20 mm Hg are considered abnormal and pressures greater than 25 mm Hg with evidence of organ failure indicate the urgent need for intervention. Strategies to intervene should begin with decreasing the rate of fluid administration. If the patient has full-thickness burns on the abdomen or torso, escharotomies should be performed. The bed should be reclined and a chemical paralytic can be given to relax the musculature. If elevated bladder pressures remain despite these maneuvers, a decompressive laparotomy is often required. Some surgeons will attempt decompression with a suprapubic peritoneal drainage catheter; however, the morbidity of these procedures is significant in burn patients. Therefore, attempts should be made to minimize fluid overload with early vigilant monitoring of fluid administration.

When patients are difficult to resuscitate, additional monitoring devices can be used including monitors of cardiac output and cardiac index. Examples include esophageal Doppler, bedside echo as well as transthoracic echo. Serial echo examinations after providing a fluid bolus allow monitoring of cardiac filling, IVC variation, and wall motion changes.^{53,54}

Tetanus Prophylaxis

Burns are considered tetanus-prone wounds and therefore tetanus status should be obtained upon presentation. Previous immunization within 5 years requires no treatment whereas immunization within 10 years requires a tetanus toxoid booster and unknown immunization requires both.

Escharotomies

Thoracic escharotomy is rarely required, however, if a patient has early respiratory distress, this may be due to compromised ventilation caused by chest wall inelasticity. If chest wall compliance is limited due to eschar, thoracic escharotomies should be performed bilaterally in the anterior axillary lines with additional release under the costal margin. Extremity escharotomy can be limb or digit saving. Edema of the underlying tissue under the thick, stiff eschar can produce vascular compromise. Though Doppler and pulse oximeters can be used to follow perfusion, once perfusion is lost, it is often too late to intervene. Thus, patients with circumferential full thickness extremity burns should have an escharotomy as soon as their airway is stable and vascular access has been obtained. Extremity escharotomy should be carried out medially and laterally and should extend the entire area of the full thickness burns. Additional compartments to assess include the orbital compartment. Ophthalmology should be consulted in large volume fluid resuscitation to assess intra-ocular pressure. If abnormally elevated, a lateral canthotomy should be performed.

BURN SEVERITY

For full-thickness burns and partial-thickness burns, identifying the extent of the burn injury is crucial. TBSA is useful to guide fluid resuscitation administration and defines the overall prognosis of patients. Only partial- and full-thickness burns are totaled to calculate TBSA.

Figure 12-2. Rule of 9s used to estimate percent burns in adults (A), children (B), and infants (C). (From *Stedman's Medical Dictionary for the Health Professions and Nursing, Illustrated, 6e*. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

If small areas in various distributions are affected, it may be easier to use the patient as a ruler with

one palm size (patient's) representing 1% TBSA. Another useful guide is the rule of 9s, where the adult body is partitioned into several areas that each constitutes 9% of the TBSA (Fig. 12-2). Regions on the adult that constitutes 9% of the TBSA include the head and arms, while the legs, anterior trunk, and posterior trunk account for 18% of TBSA each. In children and infants, the body surface area of the lower extremities constitutes a lower percentage while the head is higher. Careful estimation of TBSA is essential for proper early management of burn patients, as patients who have burns of more than 20% TBSA commonly require IV fluid resuscitation.

Acute burn injuries require prompt intervention and serial examinations. On initial evaluation, it is important to recognize and treat constrictive circumferential burns that can lead to tissue ischemia and subsequent necrosis by limiting perfusion to the distal tissues.⁴⁶ The overarching concept, however, in acute burn care is early debridement and grafting. All blisters and nonviable tissue must be debrided upon presentation. After the initial debridement, dressing changes are initiated while the patient is stabilized from a systemic standpoint. If patients suffer from full-thickness or deep partial-thickness injuries, debridement and grafting within 72 hours should be the standard of care.

First degree or epidermal burns. These burns only involve the epidermis and therefore do not blister. They do, however, have erythema and can cause pain. These burns will often desquamate by days 4 to 5.

Superficial partial thickness (second degree). Superficial partial thickness burns include the upper layers of the dermis and usually form blisters at the interface of the epidermis and dermis. When the blisters are removed, the wound is pink and wet and often is the site of significant pain. The wound should blanch with pressure and the hair follicles should be visible. Assuming no infection sets in, these burns should heal on their own in 3 to 4 weeks. They can be treated with xenograft to decrease pain.

Deep partial thickness (second degree). Deep partial thickness burns extend into the deep or reticular dermis. These will also blister, but appear a "lobster" red. The patient often has some pain and there is slow to absent capillary refill with applied pressure. The wound is often dry and if hair is present, it is usually easily depilated. These burns usually require debridement and grafting.

Full thickness (third degree). Full thickness burns involve all layers of the dermis. These burns appear white, insensate, and without capillary refill. The skin may appear depressed and leathery compared to surrounding tissues. These burns require debridement and grafting as nondebrided eschar forms a nidus for infection and inflammation.

Fourth degree. Fourth degree is used to describe burn into the deeper subcutaneous structures such as muscle, fat, fascia, and bone. These are common in electrical burns and patients who were either unconscious or insensate.

CRITICAL CARE OF THE BURN PATIENT

Hemodynamic Monitoring

Ideally, a critical care physician would be able to assess real time responses to fluid administration through accurate cardiac output readings. Unfortunately, no such noninvasive devices to directly assess cardiac output exist and those invasive devices that estimate cardiac output lack definitive studies supporting their use. Some centers use a PiCCO device which provides cardiac output based on temperature changes and use of the Fick equation, however, this requires a femoral arterial line and a large bore IJ or SVC catheter which introduce potential for complications. Some surgeons use pulse volume variation (>25% being abnormal), however, this too lacks accuracy. Though goal-directed therapies with a pulmonary artery catheter, esophageal Doppler, transesophageal echo, or CVP monitor have demonstrated promising results in some critical care populations, their use in burn patients has been mixed.^{55,56} Frequently, the output of monitors such as pulmonary artery catheters or CVP monitors fails to reflect the actual resuscitation of the patient.^{57,58}

Ventilator Strategies

Treatment for Inhalational Injury

Manifestations of inhalation injury include wheezing and air hunger. Within a few hours, the tracheobronchial epithelium sloughs and hemorrhagic tracheobronchitis develops. In cases with thermal injury interstitial edema can cause acute respiratory distress syndrome (ARDS) and oxygenation difficulty. If inhalation injury is suspected, the patient should undergo urgent airway assessment and be

placed on supplemental oxygen. Inhalation injury has three components that must be considered: (1) upper airway thermal injury which can cause swelling and obstruction, (2) CO poisoning, and (3) lower airway chemical injury from toxic agents found in smoke. Upper airway thermal injury is treated by intubation of the airway and CO poisoning is treated by 100% oxygen administration. Lower airway injury is diagnosed by evidence of soot or mucosal irritation on bronchoscopy. Airway mucosal injury from chemical pneumonitis leads to increased secretions while compromising the patient's ability to clear those secretions. This leads to increased risk of mucous plugging. Airway mucosal sloughing can also result in bleeding and clot formation that further obstruct airways. The use of aerosolized heparin, albuterol, and Mucomyst (HAM) following smoke inhalation to promote airway clearance is advocated in some centers, however, larger studies are needed to validate these treatments.^{53,54,59-61}

Early endotracheal intubation and mechanical ventilator support are important in patients with inhalation injury or in large TBSA burns expected to receive large volume resuscitation. Ventilator management should follow ARDSnet protocol recommendations.^{62,63} Low volume protective lung ventilation is used to avoid barotrauma: 4 to 6 mL/kg tidal volume, peak airway pressures should not exceed 30 cm H₂O. Assess best positive end expiratory pressure (PEEP) to determine an optimal setting, but a PEEP of at least 5 should be used to avoid lung derecruitment. Consider esophageal monitor to aid in settings if the patient is obese. Recruitment maneuvers may be needed to improve oxygenation and/or ventilation. Permissive hypercapnia is preferred over large tidal volumes to avoid lung barotrauma. Limited studies have shown a potential role for high-frequency percussive ventilation in burn patients.⁶⁴ Elevating the head of bed to 45 degrees helps decrease airway swelling, prevents aspiration and ventilator-associated pneumonia (VAP) for ventilated patients. Daily mouth care with chlorhexidine should be used for ventilated patients.

Pulmonary infection occurs in 30% to 50% of patients. Patients with three of the following five clinical criteria should be assessed for pneumonia with culture samples and placed on empiric antibiotic therapy; purulent sputum production, fever, elevated white blood cell count, infiltrate on chest radiograph, and increasing supplemental oxygen requirements. If the patient has pneumonia and been in the hospital for over 48 hours, he should be treated for hospital-acquired pneumonia. Sputum or a bronchoalveolar lavage samples should be sent for aerobic, anaerobic, and quantitative cultures. Empiric antibiotics including coverage of *Pseudomonas* sp. should be started until culture results become available. Empiric treatment should also cover methicillin resistant staphylococcus aureus and thus vancomycin or linezolid is preferred. If vancomycin is used, drug levels should be followed to adjust dosage and avoid renal toxicity.

Ventilator-Associated Pneumonia

Staphylococcus aureus and *Streptococcus* are common causes of early VAP. *Pseudomonas aeruginosa* is the most common cause of late VAP. The usual signs of pneumonia (fever, purulent sputum, or leukocytosis) are not helpful in burn patients since almost all patients are febrile, tachypneic, and have elevated white blood cell counts. The best diagnostic test is bronchoscopy-obtained bronchial alveolar lavage sample with quantification of bacteria. Bacterial counts of $>10^3$ colony forming units (CFU) are considered positive. ABA recommendations for length of VAP treatment are 8 days of antibiotic therapy for antibiotic-sensitive organisms and 15 days of therapy for multidrug-resistant organisms.⁶⁵ Consideration should be given to antifungal therapy (Diflucan) if the patient does not respond to prolonged broad-spectrum antibiotics.

Electrolyte Abnormalities and Acute Renal Failure

The immediate effects of burn injury on kidney function are secondary to hypovolemia and circulating inflammatory mediators. The diuresis phase occurs at 48 to 72 hours after "third space" fluid is reabsorbed. Hyponatremia is often seen due to large volume resuscitation with hypotonic IV fluids and will usually self-correct. Open burn wounds or the use of topical silver nitrate can also cause hyponatremia. Renal hypoperfusion exacerbates hyponatremia by decreasing glomerular filtration. Hypernatremia may also occur due to insensible and evaporative water losses. Hypophosphatemia can result from dilution or refeeding syndrome. Hypocalcemia can result from use of silver nitrate.

Acute Kidney Injury

4 Risk factors include sepsis, large TBSA burns, organ failure, and antibiotic administration. Renal function is compromised by hypoperfusion, pharmacologic nephrotoxic insult, and sepsis which are all common following major burn injury. Physiologically there is a decrease in renal perfusion, glomerular

filtration rate, and renal blood flow. The renal medulla is the most sensitive to hypoxia with damage to renal tubular cells. Patients present with oliguria and decreased creatinine clearance. Early renal failure often results from hypovolemia-induced ischemic injury. However, overresuscitation can also compromise renal perfusion by causing abdominal compartment syndrome. Late renal failure occurs after the fifth postburn day and is frequently caused by sepsis or nephrotoxic antibiotics. Continuous renal replacement therapy and pharmacologic treatments such as dopamine have not definitively been shown to improve outcomes.

The initial care of acute renal failure patients should focus on reversing underlying causes and correcting any fluid and electrolyte imbalances. The physician should ensure adequate volume status, avoid nephrotoxins, and dose medications appropriately.

Metabolic Response and Nutrition

Early nutrition is now the cornerstone of burn care. Tube feeding should begin soon after admission. Attempts to feed postpyloric should be done, however, gastric feeding is also acceptable. Tube feeds are often needed even in patients who are able to feed themselves due to the need to enable wound healing and keep up with the hypermetabolic response to burn injuries. Feedings can be continued during surgery as long as prone positioning is not planned.

The metabolic rate is significantly greater in burn patients than in other critically ill patients and leads to accelerated lean body mass wasting. Positive nitrogen balance is key to prevent skeletal muscle breakdown and highlights the importance of early nutritional support. The general composition of enteral feeding should include at least 60% calories from carbohydrates not exceeding 1,600 kcal/day, 12% to 15% from lipids and essential fatty acids, and 20% to 25% from protein. Failure to meet large energy and protein requirements can impair wound healing and alter end-organ function. Even though adequate nutrition is crucial, overfeeding must be avoided. A randomized, double-blind, prospective study demonstrated that aggressive high-calorie feeding with enteral and parenteral nutrition was associated with increased mortality.⁶⁶ The daily caloric requirements can be calculated using the Curreri formula: $([25 \text{ kcal}] [\text{body wt kg}]) + ([40] [\% \text{ TBSA area burn}])$ 1 to 2 g/kg/day of protein for synthetic needs of the patient. Burn patients should receive a small proportion of calorie requirements from fat than other ICU patients. The liver in a burn patient produces less very low density lipoprotein causing hepatic triglyceride elevation. Increased fat leads to increased complications including fatty liver, infection, hyperlipidemia, hypoxia, and mortality. Decreased gastrointestinal absorption and increased urinary losses can also lead to deficiencies in vitamin C, E, zinc, iron and selenium. Burn patients, like a subset of trauma and gastrointestinal surgery patients have been shown to benefit from glutamine supplementation.

5 Acute response to thermal injury is biphasic with the hypodynamic shock state at 24 to 72 hours and hyperdynamic catabolic state beginning on the fifth postburn day. Patients have supraphysiologic cardiac output, elevated body temperature, supranormal oxygen consumption, supranormal glucose consumption and altered glucose metabolism, increased CO₂ production, and accelerated tissue catabolism. This response is thought to be caused by excessive release of catabolic hormones including catecholamines, glucagon, and cortisol. There is a shift from anabolic–catabolic homeostasis to hypercatabolic state requiring increased substrates for energy. The resting metabolic rate is directly related to the severity of burn injury and a persistent hypermetabolic state is unsustainable. This hypermetabolism can be reduced by promptly treating sepsis as well as performing early excision and grafting of burn wounds. Recent studies have shown efficacy of a nonselective beta-blocker such as propranolol which inhibits the effect of catecholamines and slows muscle catabolism. Herndon et al⁶⁷ demonstrated that propranolol in acute burns in the pediatric population improved net muscle synthesis and increased lean body mass. Additionally, current standard of care includes providing pharmacologic agents such as oxandrolone (testosterone analog given 0.1 mg/kg q12h). Oxandrolone improves muscle synthetic activity, increases expression of muscle anabolic genes, and increases net muscle protein synthesis improving lean body mass composition and has been shown to reduce weight loss, improve donor site wound healing, and decrease hospital stay. Patients with burn injuries greater than 30% should receive oxandrolone for 6 months as the hypermetabolic state has been shown to persist following major burn injury. Despite being well tolerated, patients on oxandrolone should have liver function tests monitored weekly. Human growth hormone and insulin-like growth factor have also been investigated but results have been indeterminate.

Glucose Control

Burn injury results in an increase in hepatic gluconeogenesis and impaired insulin-mediated glucose transport into skeletal and cardiac muscles and adipose tissue. Hypermetabolism seen in burn injury also leads to hyperglycemia and insulin resistance and thus glucose should be monitored in large burn injury patients. Currently, data do not support strict glucose control (<110 mg/dL) but moderate blood glucose control is recommended (<180 mg/dL) and may decrease infectious complications.⁶⁸

WOUND MANAGEMENT

There are a variety of burn wound dressing materials. Patient factors such as burn wound depth, condition, location of the burn, and comfort during dressing changes dictate the choice utilized.⁴⁷ Although the indications for systemic antibiotic therapy have not been clearly defined, use of antimicrobial dressings is recommended. Silvadene (silver sulfadiazine) is a silver-containing cream that has broad-spectrum coverage against both gram-negative and positive bacteria. Silvadene is commonly used on the skin of both partial- and full-thickness burn injuries. Its use is contraindicated in patients with sulfa allergies and over wounds near the eyes.⁶⁹ A self-limited leukopenia is commonly seen during the initial days of Silvadene treatment, but its use can be continued as leukocyte counts recover quickly without intervention. Sulfamylon (mafenide acetate) is an analogous agent that is used over cartilaginous areas such as the nose or ear due to increased tissue penetration compared to other dressing materials. Since topical Sulfamylon cream can be used without secondary dressing, it can be used for open burn wound therapy and regular examination of the burn wound surface. Both the cream and a 5% solution of Sulfamylon are equally effective.⁷⁰ Sulfamylon cream is useful for ear burns when there is risk of cartilage exposure. Sulfamylon may cause increased pain in the burn wound. In addition to the cream, Sulfamylon soaks can also be used for burn and postoperative dressings. Patients receiving large surface area Sulfamylon dressings should be monitored for complications such as hyperchloremic metabolic acidosis that can occur due to its mechanism of action as a carbonic anhydrase inhibitor.

Silver nitrate can also be used by soaking dressings in a 0.5% to 1.0% concentration solution and applied 3 to 4 times a day. These dressings offer several advantages over Sulfamylon soaks as they cover fungus in addition to bacteria and are more cost effective. If not careful, however, silver nitrate does cause significant staining of anything it contacts. If grafts are placed in an area with surrounding cellulitis, silver soaks can be used during the first few days when the compressive dressing is still needed.

Bacitracin and Xeroform are additional examples of antimicrobial-type dressing regimens and can be used after the first dressing takedown. While both can be used anywhere on the body, bacitracin is commonly used for facial burns.

For patients who are at lower risk of infection based on the appearance of burn wounds, dressings may be changed with less frequency to achieve a balance between pain control and the need for wound coverage. Acticoat is one such option that is mainly used in partial-thickness burn injuries. This dressing consists of silver-impregnated sheets that have antimicrobial properties and can be changed less frequently, reducing pain and cost.⁷¹ The nanocrystalline particles in Acticoat are able to reduce wound infection and promote wound healing compared to older silver products, including silver nitrate.⁷² When using Acticoat, it is important to remember to moisten it with water and not normal saline as sodium can inactivate the silver. There are other commercial products in addition to Acticoat that utilize the principle of nanocrystalline dressings. These dressings can be attached with mild adhesive (Mepilex), wrapped or placed on like a glove (Silveron).

While dressing changes are sometimes used to optimize a wound before and after operative interventions, dressings also have the potential to completely heal a wound without the need for surgical intervention depending on the overall appearance of the burn and patient as a whole. Thus, a proper wound care team must not only include a critical care physician and surgeon, but it must also include a specialized wound care nurse to appropriately address this central modality of care for any burn patient.

Donor sites can be the most painful area for the patient and thus consistent donor site care should be provided. Like other wounds, these wounds heal in a moist environment and though dry Xeroform can be used, this can be extremely painful for the patient. We prefer a non-adherent dressing like mepilex that maintains wound moisture in addition to having an antimicrobial silver.

OPERATIVE INTERVENTIONS

Excision and Grafting

After initial stabilization of the patient, which generally takes 24 to 48 hours, surgical intervention should occur as soon as possible since there are no benefits to delaying surgery when it is clear that a burn wound is of sufficient depth that it will not heal on its own.^{73,74} Early excision of devitalized tissue appears to reduce the local and system effects of mediators released from burned tissue, thus reducing the progressive pathophysiologic derangements. Excision also removes dead skin which can serve as a nidus for wound infection. Tangential excision with a sharp blade on a guarded device removes necrotic tissue while preserving as much of the underlying viable tissue as possible. For large burn wounds, debridement should occur within 2 to 4 days of the initial injury. If there are insufficient donor sites to autograft all of the burn wounds, the debrided wound should be covered temporarily with allograft.⁷⁵ Alternatively, the burn can be completely excised within the first several days after injury, and a temporary skin substitute can be used to close the wound remaining after available autologous skin has been harvested and grafted (Fig. 12-3). Sequential debridement and grafting is the backbone of burn care in those suffering from large TBSA burns. The use of allograft also allows the surgeon to assess the depth of the injury and the adequacy of excision. If the homograft has good take, then it is likely an autograft will also take.

Figure 12-3. Full-thickness friction burn staged with integra to allow for full declaration of the wound prior to grafting. Top row shows initial injury. Middle row shows integra placement and bottom row shows after final debridement and graft.

During tangential excision, tissue is debrided until healthy, bleeding tissue is reached. Hemodynamic stability and correction of hematologic and metabolic derangements are helpful for such operative cases given the large amount of blood that may be lost during debridement. A discussion in the preoperative time out should take place between the surgeon and anesthetist about the amount of blood loss expected, the blood products available, and the transfusion triggers for the case. Arterial lines as well as large bore IVs and often a central line should be in place prior to beginning the operation. In general, hemoglobin fluids are not an accurate during acute blood loss anemia caused by intraoperative bleeding after a large debridement. In any burn over 20%, a preoperative blood type and crossmatch should be performed and packed red blood cells should be placed in the operating room to avoid intraoperative acute blood loss anemia. Several measures can be used to decrease intraoperative blood loss, but the

need to debride to bleeding tissue makes bloodless surgery impossible. Techniques to decrease blood loss include the use of tourniquets on the extremities as well as the use of topical spray thrombin and epinephrine-soaked Telfa pads placed immediately after excision followed by wrapping this area with epinephrine-soaked Kerlix gauze. We use 1:1,000,000 epinephrine in a saline solution as a hemostatic dressing after excision. In regions where circumferential wrapping cannot be performed, epinephrine solution can be used as an injectable solution to perform dermatoclysis. An 18G spinal needle on the end of a 60-cc syringe or tumescent device can be used to deliver this solution under the skin in areas of bleeding. Similarly, we use epinephrine injection solution as a preharvest tumescent solution for donor sites. This helps create a flat surface on which to run the dermatome and decreases postharvest blood loss. If working on an extremity, a good strategy is to start proximally and perform the excision followed by inflation of the tourniquet. Subsequently, the distal excision can be performed under tourniquet control.

In addition to achieving a healthy and well-vascularized wound bed after debridement, it is also essential to classify and examine the wounds further during this process. At this time, the distinction between superficial and deep partial-thickness burns must be made. While superficial partial-thickness injuries can heal on their own with dressing changes and without grafting, deeper burns must be treated with skin grafting. Given the association between early debridement and grafting with improved functional- and scar-related outcomes, the earlier this distinction is made the faster a treatment plan can be formulated.

Figure 12-4. Grafting back of donor site with 4:1 split-thickness skin graft. (Top) Intraop placement of graft back. (Bottom) 4 weeks postop from graft back.

Grafting exists in many forms and decisions on coverage material and thickness of graft must be made in a strategic fashion to optimize functional and aesthetic outcomes. The gold standard is to use the patient's own tissue or autograft for reconstruction. These grafts can be excised in thicknesses ranging from 0.008 to 0.018 in, with 0.012 in as a standard. Thinner grafts are helpful if the surgeon is planning to reharvest donor sites or if the patient has thin skin due to increased age or chronic immunosuppression, as thin grafts lead to faster donor site healing. Thinner grafts increase the likelihood of skin graft take and decrease the risk of superficial epidermolysis of the graft, however, thin grafts also lead to greater secondary contracture. In patients where delayed donor site wound healing is expected such as elderly patients and patients on chronic immunosuppressives, grafting back the donor site with 4:1 meshed grafts can accelerate healing (Fig. 12-4).

After a decision regarding the use of allograft versus autograft has been made, attention is turned to the size and thickness of the skin graft. Commonly, split-thickness skin grafts (STFG) composed of the epidermis and a thin layer of dermis are utilized to minimize donor site morbidity and optimize graft take. Thin grafts are more likely to succeed than thick grafts as it is easier to adhere and for neovascularization to occur. There are certain areas, however, where split-thickness grafts should not be used since they cause greater secondary contracture and less color match over time as compared to full-thickness grafts. Areas of function, such as the hands and feet, lose a remarkable amount of utility if afflicted by scar contracture and may benefit from full-thickness grafts.⁷⁶ If split-thickness skin is used on the feet and hands, the grafts should be harvested on the thick side and meshing should be avoided if possible (Fig. 12-5). Similarly, aesthetically important areas, such as the face, are also more amenable

to full-thickness skin grafting (FTSG) to optimize color match and minimize contracture.⁷⁷ If the cheeks or periorbital regions are involved, (FTSG) should be placed prior to the development of ectropion which can be extremely difficult to treat. The abdomen can offer a site for large full-thickness harvest using an abdominoplasty incision (Fig. 12-6). Full-thickness grafts, nonetheless, are limited by increased donor site morbidity due to the need to obtain both the epidermis and dermis and also require closing the tissues primarily to avoid additional wounds. There is also more difficulty with successful and complete healing of the graft given that a more robust blood supply within the wound bed is necessary to optimize take of this thicker piece of tissue. Both full- and split-thickness grafts can be meshed to increase the surface area that may be covered. Commonly performed in a 1:1 or 1:1.5 ratio, meshing also allows for fluid egress, which minimizes the risk of fluid accumulation beneath the graft, a common cause of skin graft failure. Meshing should not be performed over cosmetically sensitive areas given that the meshed pattern will be quite apparent even after complete healing has been achieved. Both types of skin grafts should be bolstered once placed to minimize shear, improve contact, and allow for imbibition and inosculation.

Figure 12-5. Sheet grafting of full-thickness hand burns. In general meshed grafts should be avoided on the hands and across important joints to avoid scar contracture. (Left) Preop photo. (Middle) Intraop photo. (Right) 1-month postop photo.

Figure 12-6. Use of full-thickness skin graft to prevent facial ectropion. Full-thickness graft harvested from the abdomen. (**Left column**) Intraop photos. (**Middle figures**) Intraop donor site photos. (**Right column**) Postop 2-week photo.

When burn injuries lead to large regions of exposed tendons, especially in the distal 1/3 of the lower extremity, free tissue transfer is often required (Fig. 12-7). It is necessary to ensure all dead tissue is debrided prior to coverage with a free flap to mitigate infection and flap failure. Additionally, if the patient is elderly or has vascular insufficiency, a preoperative computed tomography angiogram should be obtained.

In larger burn wounds, patients may not have an adequate surface area available for donor sites. In such cases, allograft can be used for initial coverage. This homograft will serve as a temporary coverage and its take will ensure that the initial excision was performed at the correct depth. Allografts will eventually be rejected as the body recognizes the newly engrafted skin as foreign material after 10 to 13 days. The process is initiated by the placement of the allografts, which is associated with an inflammatory process, leading to the activation of the innate immune response. Donor dendritic cells migrate from the graft to the recipient's secondary lymphoid organs where they present donor antigens and elicit an adaptive immune response. This response results in activated effector T cells from the donor leaving the secondary lymphoid organs and infiltrating the graft where they mediate the rejection of the allograft.⁷⁸

If insufficient autograft exists even after temporary allograft, the surgeon should consider use of cultured epidermal autografts. Cultured epidermal autografts utilize the ability to grow keratinocytes in vitro to generate cohesive sheets of stratified epithelium, which maintain the characteristics of authentic epidermis. This technique was developed by Rheinwald and Green in 1975.⁷⁹ A 3- to 4-cm² sample is taken usually from the axilla or pubic area at the time of initial debridement, and epidermal cells are isolated from the small skin biopsy and plated onto a layer of feeder cells that act as a supporting "feeder layer."⁸⁰ The feeder layer supports optimal clonal expansion of proliferative epithelial cells and promotes keratinocyte growth. Under optimal growth conditions, keratinocytes initiate growing colonies and after 3 to 4 weeks, the cultured epidermal autograft sheets are 8 to 10 cells thick.^{81,82} These constructs require advanced planning as it takes at least 3 to 4 weeks to develop. Additionally, risks and benefits should be discussed with the family and patient as there is a high percentage of graft loss due to fragility. Furthermore, case reports of squamous cell cancer developing from cultured epidermal autograft sites exist.

Order of Coverage

6 The first operations performed in large burn patients set the stage for how quickly a patient will recover. The first priority should be to excise all eschar and achieve coverage, with autograft if available or with allograft if not available. In patients with large TBSA burns, it is crucial to get the back excised and covered first as delay of this step will make it difficult to have a patient stable enough to tolerate a prone position. Additional strategies to improve coverage of the back include the use of autograft meshed 3:1 covered with allograft meshed 2:1 and a secure bolster placed over top. This minimizes shear and loss of the autograft. Early coverage of the back and avoidance of prone positioning may also mitigate the need to perform an early tracheostomy. Once the posterior areas of the patient are excised and covered, then attention can be turned to the anterior regions and the extremities.

Figure 12-7. Use of free anterolateral thigh flap for reconstruction of lateral full-thickness ankle burn with exposed tendon. Top left shows initial injury. Middle left shows ALT flap inset. Bottom left shows final ALT placement. Top right shows ALT donor site intra op. Middle right shows donor site 1 week postop. Bottom right shows ALT 1 week postop.

Extremity Treatment

Burns of the hands and feet often require a multidisciplinary approach with involvement of therapists, hand and plastic surgeons. Early evaluation must verify adequate perfusion. Extremity elevation benefits hand burns by limiting edema and active range of motion is necessary to maintain function. Splinting should put the axilla at 90 degrees, elbow in extension and hand in intrinsic plus with the metacarpophalangeal joints at 70 to 90 degrees and the interphalangeal joint and the wrist in 20- to 30-degree extension.

Palmar hand or plantar foot burns occur on specialized skin and are composed of a thicker dermal layer and thus should be managed conservatively. If after 3 to 4 weeks no healing has occurred, full thickness burns should be considered. Small palmar digit burns can be treated with a full thickness hyperthenar graft.

Though the hands and feet are important to excise and cover early, these areas require the use of sheet or 1:1 meshed grafts. These areas should not delay the coverage of large areas such as the back which can use widely meshed grafts. More important, for the digits, is the use of early K-wire fixation in the intrinsic plus position in deep burns to the fingers. K-wires should be placed in the fingers to keep them in the intrinsic plus position: MC flexed at 70 to 90 degrees, wrist 20 to 30 degrees, IP joints in full extension, and thumb kept abducted and slightly opposed. This will help prevent severe joint flexion contractures which can lead to the loss of digits if straightened in a delayed fashion.

Genital Burns

Genital burns should be investigated for abuse in children. Burned foreskin must be reduced to a normal position to avoid paraphimosis. Penile and scrotal burns will often heal without excision and grafting. Bladder catheterization and urethral stenting is not required for genital burns and increase the risk of infection.

Skin Alternatives

Integra is a newer alternative for temporary coverage and creation of a neodermis in a wound after debridement. Composed of bovine collagen and silicone film, this construct is designed to mimic the epidermis and dermis of the missing tissue.^{75,83} Its structure allows for the growth of healthy granulation tissue into a wound bed to optimize the wound niche to promote greater and healthier take

of the skin graft that will eventually be placed over the site of injury. This is especially important over areas of function, such as the hand, which has the potential for significant debility if scar or graft contracture occurs over the traumatized site. Integra is also important for areas that do not have enough viable or vascularized tissue to support a skin graft (Fig. 12-3). Integra, however, often fails in burn patients due to infection and requires constant soaks with Sulfamylon. Additionally, clinicians should examine the Integra frequently and remove any areas of silicone under which there is concern for infection.

Figure 12-8. Xenograft treatment of superficial partial-thickness burn to avoid use of STSG and to improve pain. (Top, left) Intraop photos of superficial partial-thickness burn. (Top, right and bottom, left) Placement of xenograft over burn using interrupted absorbably sutures. (Bottom, right) 1-month postop from xenograft placement.

Porcine xenografts are an alternative to dressing changes alone in superficial partial-thickness burn wounds. In wounds that are likely to heal by themselves taking the patient to the operating room, performing a good debridement under anesthetic, and placement of xenograft to the burn wound can be beneficial (Fig. 12-8). The xenograft can minimize pain, improve wound healing, and de-escalate the complexity of dressing changes. This benefit is greatest in children or patients with tolerance to narcotic pain medications due to excessive pharmacologic supplementation prior to becoming injured.

PAIN CONTROL

Acute Pain

Burn injuries are among the most painful traumatic injuries sustained given their extensive nature. Thermal injury to the overlying epidermis leads to exposed nerve endings which are sensitive to stimulation. Thus, superficial partial-thickness burn injuries often cause the most pain to the patient. Deeper partial-thickness and full-thickness injuries may not cause as much pain to palpation; however, these regions are still painful due to the inflammatory response. Given the multifactorial nature of burn pain, elimination of pain in burn patients is not possible. Outcomes are often improved if a dedicated physician with expertise in pain management is part of the burn team. When establishing a pain regimen, the physician should focus on treating acute as well as chronic pain. A successful regimen often includes the use of short- to intermediate-acting narcotics to treat acute pain as well as a long-acting narcotic such as methadone for chronic pain. Procedural pain during dressing changes can be treated with short-acting narcotics. Some patients will also benefit from Neurontin to alleviate neurologic pain. Additional studies are underway to investigate the use of Seroquel for patients with a large anxiety component associated with their pain. Balancing of narcotic dosing over time is essential to preserve

their acute pain relief effect and to avoid situations in which tolerance renders all available agents and doses ineffective.

Chronic Pain and Substance Abuse

The burn patient population that is admitted with underlying substance abuse and alcohol dependency is a particular challenge for the burn team to successfully treat with regard to pain relief. In such circumstances, the team should have high vigilance for symptoms of drug or alcohol withdrawal. New studies are investigating prophylactic treatment with barbiturates to prevent alcohol withdrawal rather than currently used strategies which are largely reactionary and treat withdrawal after symptoms occur. Involvement of psychiatrist or pain specialist in the prescription of these drugs is beneficial. Methadone can also serve as a helpful adjunct for patients with chronic pain given its decreased addictive potential relative to other narcotics.

INFECTIONS

Wound Infections

Burn wound sepsis is a severe sequelae of burn injuries caused by colonization of the damaged skin and soft tissues with infectious bacteria or fungi. The most common organisms are *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*. Despite the morbidity of this complication, its incidence has decreased dramatically with the use of early excision and grafting and appropriate topical antibiotics therapy. If burn wound infection is suspected, wound dressings should be taken down and a quantitative culture should be obtained. A bacterial count of greater than or equal to 10^5 colony-forming units bacteria/gram of tissue is considered significant infection, though the data from which this number was derived date back to the 1960s. General critical care infection protocols should be followed with burn wound debridement if the patient does not yet have skin grafts placed. If adequate excision has been performed and the patient already has skin grafts placed, then antibiotic soaks or cream dressing changes and IV antibiotics will often help combat infection. Quantitative cultures should be obtained every 3 to 4 days when treating burn wound infection to gauge progress and allow for escalation or de-escalation of treatment.

Vascular Catheter–Related Infections

Central venous access should be obtained using sterile technique and antibiotic-impregnated catheters as these have proven efficacious in the general critical care population⁸⁴ (ref is Pronovost/Keystone). Additionally, central venous catheters should be placed in nonburned areas if possible. Routine changing of catheter after a specific time period has not been shown to improve outcomes. However, close attention should be paid to catheters in place for over 7 days, especially in burn areas if the patient is febrile and has signs of systemic infection. If a catheter-related infection is suspected, two peripheral blood cultures should be drawn. A culture specifically from the catheter does not improve diagnosis or outcomes. Despite the increased use of PICC lines, these catheters have equal if not increased risk of infection relative to central venous catheters.

Pneumonia

Along with increased survival of burn patients comes increased time burn patients are on the mechanical ventilator. Increased incidence of pneumonia is seen with inhalation injuries and prolonged intubation and mechanical ventilation. As in other critical care populations, an emphasis should be placed on daily awakening and extubation/spontaneous breathing trials. Additionally, all patients on the ventilator should have their head of bed elevated greater than 30 degrees and daily chlorhexidine mouthwashes may be beneficial. If a pulmonary infection is suspected, a CXR should be performed and a quantitative culture specimen should be obtained from the bronchial tree. A quantitative result greater than 10^3 is considered positive and should be treated.

Deep Vein Thrombosis

The dangers and need for prophylaxis in general surgical and burn patients have been highlighted in recent studies. Burn patients have increased risk with increased number of operations, pneumonia, and central venous access. All inpatients should receive prophylaxis with heparin 5,000 U three times a day

or weight-based enoxaparin daily (PMID: 21979849).

BURN RECONSTRUCTION

Optimizing Acute Treatment to Minimize the Need for Reconstruction

As in any plastic and reconstructive surgery case, meticulous planning and foresight is imperative. During the acute burn injury stages, emphasis should be placed on general coverage of burn wounds and large flaps and local tissue rearrangements should be delayed. If there is a high likelihood that the patient might need a flap or local tissue rearrangement in the future, the region of graft harvest should be carefully planned. For example, if a patient has a large neck burn or exposed lower extremity tendons or bone and if an anterolateral thigh flap would help, then the thigh should be avoided as a donor site. Surgeons should consider the fact that a meshed skin graft will have an abnormal appearance once it heals as well as causing increased hypertrophic scarring. Donor sites should be harvested from inconspicuous locations in case a hypertrophic scar results. Other examples requiring acute reconstructive surgery include eyelid contracture with exposure keratitis and cervical contractures causing airway issues. Once acute grafts and donor sites have healed patients and physicians should focus on maximizing normal scar healing. Normal wound healing requires a balance in the hydration of the wound and water-based moisturizers should be encouraged. Silicone sheeting or other occlusive dressings can help in early hydration of the wound.⁸⁵⁻⁸⁷ Additionally, attempts should be made to minimize tension off of the scar with potential applications of new devices. Compression garments are also commonly used to decrease formation of hypertrophic scarring, though their efficacy is still debated.^{88,89}

Hypertrophic Scarring

Thermal burn injuries can cause tremendous morbidity, leaving the patient with not only cosmetic but also functional impairments. Hypertrophic scarring is a major complication after burn injury with a prevalence of 32% to 72%. Several risk factors have been identified that contribute to its development including the localization of the burn injury, burn depth, time to heal, and skin color.^{90,91} While the precise mechanism by which hypertrophic scarring occurs by remain unclear, strong and persistent expression of transforming growth factor beta (TGF- β), focal adhesion kinase-1 (FAK1) and its receptors have been associated with postburn hypertrophic scarring. Furthermore, a critical step in the healing process that is altered is the transition from granulation tissue into normal scarring. During this remodeling process, wound epithelization and scar collagen are formed but accompanied by a gradual decrease in cellularity due to apoptosis. However, early immature hypertrophic scars caused by burns are hypercellular and during the process of remodeling and maturing, fibroblast density does not resemble that of normal healing.⁹² Apoptosis of myofibroblasts occurs 12 days after injury in normal wound healing, but in hypertrophic scar tissue, the maximum apoptosis occurs much later at 19 to 30 months.⁹³ These events result in a significantly higher percentage of myofibroblast and hypertrophy of the scar tissue following severe burn injuries.

One of the key pathologic factors that must be addressed in any hypertrophic scar is tension. A new concept of “scar rehabilitation” has emerged with the key idea being to improve the environment of the scar without actually excising the scar. The most important step in rehabilitating the scar is release of tension. Rather than excising the scar, this involves just releasing the area of greatest tension. Despite not removing any tissue, a large defect is often created once the tension is released. This defect can then be treated by adding new tissue such as a FTSG or a thick STFG. Additional ways to relieve tension involve the use of tissue rearrangements such as a Z-plasty. A Z-plasty lengthens the scar at the expense of width alleviating tension along the central axis of the hypertrophic scar. In general Z-plasty rearrangements are made with 60-degree angles to maximize tissue gain without causing excess tension on the donor site closure. Alternative V-Y advancements are useful if there is healthy tissue surrounds the scar and can be advanced into the area of the contracture release. Both Z-plasties and V-Y advancements relieve tension on the scar that help create the hypertrophic environment. By relieving this tension, the scars can heal in a more normal environment and often will do so without the raised erythematous characteristics initially present. The physiology of the Z-plasty is thought to result from improved collagen remodeling after relief of tension.^{94,95} Z-plasties can be used to flatten a hypertrophic scar or elevate a depressed scar as long as the lateral limbs extend into normal tissue. The classic design of a Z-plasty has a central segment with limbs oriented at 60 degrees (although can be 30

to 90 degrees) with all 3 lines of equal length (Fig. 12-9). Widening the angle of the limbs increases percent gain in length along the central limb. Multiple Z-plasties can be designed in series to improve contracture release in large hypertrophic scars.

Although less well studied, postburn pruritus is another significant problem affecting almost 100% of pediatric and 87% adult patients and may persist for many years, resulting in a scratching/inflammation cycle leading to hypertrophic scarring. Treatment options are limited for postburn pruritus, commonly involving antihistamines and moisturization of the skin with only incomplete resolution of symptoms and thus significant deterioration in quality of life.⁹⁶

Current treatment strategies for hypertrophic scars include surgical manipulation, intralesional corticosteroid injection, cryotherapy, and laser therapy. Surgical manipulation to remove the excess skin remains the traditional treatment for hypertrophic scar. Recent studies investigating the role of fat grafting into scars have shown promise to further improve function and appearance.⁹⁷ Patients who have undergone fat transfer reported satisfactory results 6 months after the procedure, indicating considerable improvement in the features of the skin, skin texture, and thickness. Histologic examination demonstrates new collagen deposition, neovascularization, and dermal hyperplasia in regions treated with fat grafting, which mimics surrounding undamaged skin. Intralesional corticosteroid suppresses the inflammatory process in wounds, diminishes collagen synthesis, and enhances collagen degradation.⁹⁸ Conversely, cryotherapy induces vascular damage that leads to anoxia and ultimately tissue necrosis and has yielded marked improvement of hypertrophic scars.⁹⁹ Efficacy is limited to the management of small scars.

Figure 12-9. Z-plasty diagrams demonstrated tissue rearrangement used for hypertrophic burn scars.

LASER SCAR REHABILITATION

7 Since the introduction of laser treatment in the mid-1980s, additional lasers with different wavelengths have been employed. Encouraging results have been obtained with the 585-nm wavelength pulsed dye laser (PDL), which has been recognized as an excellent therapeutic option for the treatment of younger hypertrophic scars.¹⁰⁰ PDL induces the dissociation of disulfide bonds in collagen fibers and leads to collagen fiber realignment, decreased fibroblast proliferation, and neocollagenesis. Repeated treatments, generally between 2 and 6 are required for the optimal resolution. Shorter-pulse durations are generally more effective for scar improvement.¹⁰¹ Unlike vascular malformations and hemangiomas, scars also tend to respond better to low or medium PDL fluences, about 4 to 7 J/cm², than to higher fluences.¹⁰² Low-, short-pulse duration PDL fluences induce local damage to the vascular endothelium followed by mural platelet thrombi, while high PDL fluences at longer-pulse durations tend to cause immediate intravascular coagulation with cessation of blood flow.¹⁰³ Side effects include erythema/purpura for 7 to 14 days, hyperpigmentation, and hypopigmentation. Though these lasers are

effective in improving scar erythema, they do not have a substantial effect on the thickness or contour of hypertrophic scars. Controversy still exists about how much of this redness would subside if given adequate time compared to laser treatments (Fig. 12-10).

Recently, research studies have demonstrated the benefit of fractional photothermolysis in the treatment of hypertrophic scarring. Though the exact mechanism is unknown, this concept uses a CO₂ laser (10,600 nm), which is an ablative laser that targets water in underlying tissues. The laser creates columns of tissue destruction, which stimulates collagen production in adjacent uninjured columns of tissue. Only a portion of the epidermis and dermis is treated with columns of energy in order to create targeted areas of thermal damage (microthermal treatment zones). The untreated areas are a reservoir of collagen and promote tissue regrowth. Fractional lasers, as opposed to nonfractional lasers allow for greater penetration with decreased risk of scarring. This healing will take place outside of the acute inflammation period and thus allow for a more normal wound healing cascade than existed at the time of the initial excision and graft. The adjacent uninjured tissue allows for more rapid tissue regeneration from follicles and sweat glands. Ablative lasers have a greater potential depth of treatment compared to nonablative lasers (4 mm compared to 1.8 mm). Ablative lasers appear to be more effective for thicker scars and those associated with restriction. Overall, this creates a more smooth appearance and allows meshed grafts to appear less obvious. Patients have described less tightness as well as decreased pruritus and improved overall appearance (Fig. 12-11).¹⁰⁴

Recent studies also have demonstrated the benefit of fractional CO₂ laser for pruritis. Often multi-modality treatment with PDL for erythematous scars, fractional CO₂ laser for thick and pruritic scars and local tissue rearrangement to relieve tension lead to improved outcomes (Fig. 12-12).

Figure 12-10. Pulsed dye laser scar rehabilitation.

Tissue Expansion

A tissue expander (TE) is an artificial filling device that is used to grow and expand local tissue to reconstruct an adjacent soft tissue defect. A silicone elastomer reservoir is placed beneath the donor tissue and slowly filled over time with saline, causing the overlying soft tissue envelope to stretch with a net increase in surface area per unit volume. Advantages to TE are that it allows the surgeon to reconstruct “like with like” using donor and recipient tissues that share similarities in color, thickness, texture, and hair-bearing patterns. Larger soft tissue defects that would usually require a local flap for reconstruction can be closed primarily using expanded local tissue, limiting donor site morbidity. A robust angiogenic response is achieved histologically within the expanded local tissue resembling an incisional delay phenomenon. Predictable amounts of donor tissue can be gained through the expansion process. As a reconstructive technique, it is versatile, reliable, and repeatable, and can be applied to many regions of the body.

One should use the largest expander possible with a base diameter approximately two to three times that of the diameter of the soft tissue defect to be reconstructed. If the expander contains a base plate or rigid backing, this side should be placed along the floor of the pocket to guide the direction of expansion outward. Multiple expanders are sometimes needed to reconstruct a single defect, depending on the availability of donor tissue. Rectangular expanders are useful on the trunk and extremities, and result in the greatest amount of actual tissue gain, however, these should be avoided on the scalp (approximately 40% of theoretical tissue gain). Round expanders are most commonly used in breast reconstruction, and result in the least amount of actual tissue gain (approximately 25% of theoretical tissue gain). Crescent expanders are useful in scalp reconstruction, and gain more tissue centrally than peripherally. Custom expanders are helpful for irregular defects, but may be more expensive.

Figure 12-11. Ablative laser rehabilitation.

Remote filling ports are connected to the TE via silastic tubing, and can either be placed subcutaneously (most common) for percutaneous access or externalized for direct access. It is crucial not to make the tunnel too wide or the filling port will fall and be difficult to fill. Integrated filling ports are located within the expander, although this design may increase the risk of inadvertent puncture of the outer shell. The expander is usually placed adjacent and parallel to the long axis of the soft tissue defect. If placed in the extremities, the expander should not cross any joints or impinge on joint motion. Donor tissue must be well vascularized, free of unstable scar. Expanders should be used cautiously in irradiated tissue or patients with poorly controlled diabetes mellitus, vascular disease, or connective tissue disorders. The expander pocket can be developed in the subcutaneous, submuscular, or subgaleal planes depending on the location of the soft tissue defect. The size of the expander pocket should be individually tailored to allow the expander to lie completely flat with minimal wrinkling.

Excessive dissection should be limited to prevent expander migration postoperatively, and meticulous hemostasis is important to minimize hematoma formation. Incisions are placed radial to the expander pocket to minimize tension on the incision during the expansion process. Undue tension placed on the incision during expansion can cause dehiscence and exposure of the expander. One should consider future reconstructive options when planning incision placement such that the incisions can easily be incorporated into planned flaps or the tissue to be resected. Endoscopic-assisted expander placement utilizes smaller incisions and allows more direct visualization of the expander pocket, but at the expense of a steep learning curve and altered depth perception.

Figure 12-12. Multi-modality treatment can result in improved outcomes.

The tissue expansion process usually begins 2 weeks postoperatively and continues on a weekly basis thereafter. The expander is filled until the patient expresses discomfort or the overlying skin blanches. The expansion process is complete based on surgeon preference when he/she deems there is enough donor tissue available to reconstruct the soft tissue defect. Additional “over” expansion is often recommended to ensure adequate soft tissue coverage.

Disadvantages of tissue expansion include the need for multiple operations (at least two for placement and removal of the expander) and outpatient visits. Definitive reconstruction is delayed secondary to the expansion process. Specific complications related to the presence of foreign material can be as high as 30% (e.g., infection, exposure, or extrusion). This complication risk is higher in the extremities and scalp.

Specific Anatomic Concerns

Neck contractures are the most common wound healing complication of burn injury. Functionally this can limit range of motion and oral competence. Surgical release of the scar contracture down to platysma or subplatysmal layer followed by coverage with large FTSG or thick STSG followed by aggressive range of motion 5 days after having patient in neck brace is an option for correction. If the contraction is severe, a free tissue transfer may be required after neck release. Postoperatively it is crucial to use compression garments for 6 to 18 months and neck bracing to keep the neck extended to prevent contracture recurrence.

Ectropion is a common complication after periorbital burns. This deformity is caused by inadequate tissue. If the ectropion is caused by an extrinsic contracture, scar release and provision of additional tissue are needed to prevent recurrence.

Early ectropion requires early ophthalmologic and surgical attention as it can lead to corneal abrasions. Surgically, the contracted lid should be released and a large full thickness graft should be placed ([Fig. 12-11](#)). If excess tension, a midface lift and lateral canthoplasty can provide additional support. Additionally, temporary or permanent tarsorrhaphies should be placed to protect the globe.

The axilla also represents a common area of contracture because it is difficult to maintain adequate positioning in the acute phase of burn wound healing. Anatomically the axilla can be divided into the anterior axillary fold, midaxillary line, and posterior axillary line. The Shoulder should be kept 90 to 120 degrees abduction, 15 to 20 degrees flexion (60 to 80 degrees arm elevation). There are three grades of axillary contractures:

- 1A: involves anterior axillary fold
- 1B: involves posterior axillary fold
- 2: involves both axillary folds
- 3: involves both folds and axillary dome

Type 1 and 2 contractures can be treated with sequential release and thick STSGs or FTSGs. Type 3 contractures require local and distant flaps including parascapular and latissimus flaps. It is important to pay attention to where hair-bearing regions are transposed. Postoperative occupational therapy and

splinting are necessary to prevent recurrence.

Nailed Reconstruction

Eponychial fold and decreasing range of motion of the distal interphalangeal joint (DIP). To improve the DIP range of motion and proximal to the DIPJ releasing the skin proximally and distally taking care not to injure the underlying extensor tendon. A full thickness graft is then placed (Fig. 12-12).

ASSOCIATED COMPLICATIONS OF BURN INJURIES

Muscle Catabolism and Wasting

Burn injury involving large areas of the body is associated with significant pathophysiologic sequelae, which can persist up to several years after the acute injury. There are significant changes in essential metabolic processes, which shift physiologic homeostasis to a catabolic state, resulting in loss of lean body mass. The TBSA affected by the burn injury plays an important role, since reestablishing a functional skin barrier initially takes priority and requires a protein substrate, which is often provided by skeletal muscle.¹⁰⁵

Muscle catabolism after burn injury is mediated by several factors including increased energy requirement¹⁰⁶ and heightened inflammatory state involving the systemic release of stress hormones, catecholamines, and glucocorticoids, which mediate the underlying metabolic derangements. Other factors include prolonged immobilization and the loss of a functional skin barrier, which lead to disturbed thermoregulation requiring increased energy expenditure to maintain body temperature. The consequences can have devastating effects on the convalescence of pediatric burn patients, where an increased catabolic state can lead to delayed linear growth for up to 2 years after the injury.¹⁰⁷ The physiologic response of skeletal muscle to anabolic stimuli is altered in pediatric patients with amino acid infusion therapy failing to stimulate a net protein deposition in skeletal muscle even 6 to 12 months post injury.^{108,109}

Studies investigating the effect of burn injury on physiologic changes in skeletal muscle have uncovered a critical role for mitochondrial function showing that processes involving carbohydrate metabolism, lipid metabolism, and oxidative phosphorylation are significantly altered.¹¹⁰ Righi et al.¹¹¹ demonstrated that treatment with a mitochondria-targeted antioxidant in a mouse burn model significantly increases mitochondrial ATP secretion and ameliorates oxidative stress, suggesting that reactive oxygen species play a significant role in burn pathogenesis. Improvements in skeletal muscle mitochondrial function have also been attributed to the effect of fenofibrate, a peroxisome proliferator-activated receptor- α agonist used to treat impaired glucose metabolism commonly observed after burn injury. In pediatric burn patients, fenofibrate treatment improved glucose levels and insulin sensitivity.¹¹² Other therapeutic approaches, which have shown significant benefit in clinical trials include the blockage of beta-adrenergic receptors, resulting in attenuated catecholamine effect and improved net muscle protein balance.⁶⁷ Anabolic steroids such as oxandrolone, and physical exercise have been shown to increase lean body mass in children who suffered from > 40% TBSA burn injury.¹¹³

When the body is in a prolonged catabolic state due to the increase in caloric requirements, patients must consume at least 2.5 to 3 g/kg/day of protein.⁷⁵ Nutritional shakes and high-calorie foods are a necessity to optimize the conditions for wound healing. It is important to start nutrition as soon as possible, preferentially using the enteric route. Nasogastric or nasoduodenal/jejunal feeding tubes should be inserted early in the care of this patient population. Dieticians are crucial members of the burn care team in creating individualized feeding plans and ensuring that nutrition is at the forefront of daily care. Albumin and prealbumin levels can be trended over time to ensure that adequate nourishment is achieved.

Patients should also be referred to physical and occupational therapy. A therapeutic exercise program should be implemented to maintain normal range of motion, strength, and endurance. In order to counteract the catabolic effects of burn injuries, a program of active and active-assisted exercise is necessary. Depending on the severity of the burn and the patient's willingness to tolerate the associated pain with exercise, passive range of motion exercises should be prescribed. In the event that full range of motion is not achievable, a program of stretching can be prescribed in its place. Anesthesia can be used to assist these exercises when patients cannot tolerate pain.

Range of motion exercises can also minimize skin contractures, as skin is a tissue that requires sustained mechanical stretch to facilitate lengthening of the underlying collagen and extracellular matrix

compartments. Initial skin exercises should attempt to elongate the skin with repetitive low loads with differences in length. Following this initial precondition, a prolonged stretch is applied to maximize skin laxity. Blanching is a clinical sign that capillary blood flow is impeded and is a good sign that the tissue has reached its maximum yield point. Strength exercise should follow as soon as the patient can tolerate it. Strength programs best suited for burn patients should include progressive resistive exercises. Fatigue and loss of endurance are major issues as a patient recovers. It is important to include endurance training and monitor cardiopulmonary response. Concurrently, patients should be encouraged to walk as ambulating patients have fewer lower extremity contractures, endurance problems, and venous thrombosis.

Heterotopic Ossification

Heterotopic ossification (HO) is the pathologic formation of bone in extraskeletal regions of soft tissue including muscle, joint spaces, and often encasing major nerves (Fig. 12-13). This complication of burn injury causes significant pain, joint restriction, and contractures.¹¹³ The incidence of HO is proportional to the severity of the injury with an increased incidence in severely burned patients. HO may affect all areas of the body but is most frequently encountered in the elbow joint (Fig. 12-13).^{114,115} While the etiology of HO remains elusive, common risk factors that have been identified include upper extremity burns, large TBSA burns, young age, prolonged immobilization¹¹⁶ and a delay in time to wound closure.¹¹⁷

Early detection and diagnosis of heterotopic bone formation is critical in the clinical management of this complication, which oftentimes involves surgical resection. The success rates of surgical intervention are not well established and are associated with a high recurrence rate. Perioperative radiotherapy has been suggested as an adjunct to surgical resection and has been shown to reduce the recurrence rate to some extent.¹¹⁸ While the pathophysiologic processes underlying the development of heterotopic bone formation are poorly understood, several studies have implicated increased inflammatory signaling and the involvement of progenitor cells as crucial contributing elements.

Pharmacologic interventions have been shown to have some efficacy in limiting the severity of HO. Bisphosphonates and non-steroidal anti inflammatory have been used for prophylaxis and treatment of HO with some success.^{119,120} However, there is no consensus on which drug should be prescribed and when treatment should begin. It has been proposed that bisphosphonates should be prescribed as soon as elevated alkaline phosphatase is noted or imaging studies establish the presence of HO. NSAIDs limit the severity of HO when delivered as a preventative therapy. The primary pathway thought to play a role is the bone morphogenetic protein (BMP) receptor 1 pathway; specifically the ALK2 kinase domain which stimulates canonical smad signaling. Though diagnosis is often not made until after 3 to 4 weeks after the burn injury, pathologic changes occur much sooner and thus treatments should target this early osteogenic signaling if prophylaxis is to be achieved. The effect of early active and passive range of motion on HO is unknown. Though the elbow is the most common site, the reason for this high incidence is unknown.

Figure 12-13. Heterotopic ossification.

Marjolin's Ulcer

Similar to chronic wounds from other etiologies, chronic untreated burn scars can lead to malignant degeneration. Squamous cell carcinoma is the most common type of malignancy observed. Malignancies are rare in an era of early excision and grafting. Malignancy requires wide excision with at least a 2 cm margin as well as sentinel lymph node biopsy. If the sentinel node is positive, a complete lymph node excision should be performed.

Clinical Research

Clinical research determines the safety and efficacy of medications, devices, diagnostic tools, and treatment regimens and has provided new insights to effectively care for burn patients. Within the last decade, critical care, wound care treatment, and burn reconstruction research have advanced in both diagnosis and identification of efficacious therapies to improve the overall recovery process for burn victims.

Critical care research has focused on the delivery of adequate care during the initial phase following the traumatic burn injury. Immediately following the trauma, burn patients experience severe shock due to concomitant inflammation leading to severe edema. While rigorous fluid resuscitation has been shown to increase overall survival for patients with high TBSA involvement, novel resuscitation methods have recently been investigated. In a prospective randomized study, clinicians investigated the use of colloids within the first 24 hours of resuscitation.¹²¹ Patients with a TBSA burn injury greater than 15% were either provided with crystalloid resuscitation or a mixture of crystalloid and hydroxyethyl starch. Patients given colloids required less fluid, experienced less edema, and had a lower C-reactive protein indicative of less inflammation. Additional studies have investigated the use of therapeutic plasma exchange for refractory burn resuscitation and discovered that patients had reduced lactate levels, increased mean arterial pressure, and improved urine output after treatment.¹²² Our recommendation and common practice use crystalloid rather than colloid as outcomes in burn patients have not been conclusively shown to be improved. These studies highlight the complexity of burn shock resuscitation and the need for ongoing research in the field.

Studies have investigated the role of regulating glucose levels in burn patients during the critical phase. Stress hyperglycemia after severe burn injury has long been established as a physiologic response to trauma. Recent studies have demonstrated the need for early glycemic control, as burn patients who did not have optimal glucose levels experienced increased mortality. Intensive insulin therapy in critically ill burn patients limited the number of infections and sepsis and improved overall organ function.¹²³ In general moderate glycemic control as demonstrated by the NICE-SUGAR trial appears

efficacious.¹²⁴ Delivery of insulin also decreased inflammatory responses, as noted by decrease levels of systemic IL-6 and C-reactive protein, and also improved body density, body fat, and lean body mass. Insulin therapy also reduced resting energy expenditure in the first week following the burn injury, improved mitochondrial function, and hepatic glucose metabolism.¹²⁵ Furthermore, the glucose variability experienced by a burn patient during the critical period is also associated with increased mortality rates, suggesting that consistent and tight glucose control may provide a significant survival benefit.¹²⁶ Taken together, these studies build an argument that in burn patients, glucose control with insulin therapy may reduce inflammation, improve energy utilization, and improve overall prognosis.

Another important area of research is the development of new technology to aid in wound assessment and treatment. Punch biopsy, laser Doppler imaging, and near-infrared spectroscopy have been employed to diagnosis the burn depth and severity of the primary wound site. Additional studies advocate for the use of confocal laser scanning microscopy (CLSM) due to its greater contrast and sensitivity. This technology images wounds in vivo without any physical dissection using a laser source. CLSM was able to determine wound depth by assessing the number of perfused dermal papillae and was able to accurately classify burns based on the amount of perfusion.¹²⁷ Recent development of extracorporeal shock wave treatment (ESWT) has shown promise as it promotes angiogenesis, increases perfusion, and accelerates wound healing. In a pilot study, patients treated with ESWT demonstrated increase blood flow to the burn wound within 3 weeks.¹²⁸ This therapy shows great promise, as it is a noninvasive measure to improve wound healing.

Advances in burn reconstruction have also been noted in the last decade. While TEs have been a mainstay of burn reconstruction, several studies have surveyed the use of endoscopic-assisted placement of expanders and the use of osmotic TEs.^{129,130} Both endoscope-assisted placement of expanders and osmotic TEs offer advantages over the traditional methods, as they are more cosmetically acceptable and require fewer injections, respectively. As TE technology continues to improve with new expansion techniques and devices, discovering the best technique and devices will be an important component of burn reconstruction. Cultured epithelial autografts, as discussed in previous sections, have gained interest as an alternative for cutaneous coverage for patients with large burn wounds and small potential donor sites. With final engraftment percentages as high as 73% and 90% patient survival rate, it is an attractive alternative for patients with severe and extensive burns.

BASIC SCIENCE AND TRANSLATIONAL SCIENCE RESEARCH

Basic science and translational science research in burn injuries have significantly advanced in the last 50 years and have focused on both understanding and treating the primary wound site as well as complications that arise from these traumatic burn injuries.

Wound healing can be described in three different stages: inflammation, proliferation, and remodeling phase. Hypertrophic scarring is an aberrant form of the normal wound healing process that does not extend beyond the original wound margins. Hypertrophic scar formation involves the constitutively active proliferative phase of wound healing, resulting in high vascularity and dense extracellular matrix deposition.¹³¹ Histologic studies suggest that a robust inflammatory response, involving mast cells, macrophages, fibrocytes, and lymphocytes, may underlie the excessive fibrosis seen in hypertrophic scar formation.¹³² The secretion of TGF-beta1, platelet-derived growth factors (PDGFs), and epidermal growth factor contributes to the inflammatory response and results in excessive inflammatory cell stimulation, fibroblast proliferation, adhesion, neovascularization, matrix production, and ultimately contraction.¹³³ As such, translational science research from the bench to the bedside focuses on new therapies targeted at quenching the inflammatory response, limiting fibrosis, and inhibiting angiogenesis by targeting the mediators of this scarring process.^{134,135} Additional basic science research aimed at understanding the wound healing process and translational science research investigating new treatment options will continue to advance our understanding and treatment of burn-related injuries.

Additional studies into the precise cause of secondary complications such as HO has gained significant interest due to the increase in presence of HO in veterans who have sustained combat injuries. While the precise pathophysiology behind HO is still unclear, it is thought to be related to local and systemic factors, causing osteoblastic differentiation of local cells. Previous studies have attempted to elucidate the local and systemic wound inflammatory response leading to HO, through the identification of cytokine and chemokines secreted from the wound.¹³⁶ Serum analysis demonstrated a profound systemic inflammatory response in burn patients, as burn patients maintained increased levels of IL-6 and macrophage chemoattractant protein (MCP)-1 over time. Both IL-6 and MCP-1 are

inflammatory agents that function in recruiting monocytes and macrophages to the site of injury, indicating sustained inflammation throughout the wound healing process. Furthermore, MCP-1 has also been implicated in bone remodeling and may be an earlier indicator of HO development. Locally, proinflammatory cytokine MIP-1 alpha has been shown to be upregulated, indicating robust inflammation locally. This inflammatory response is believed to enhance bone regeneration; however, the precise cells and cytokines involved for this enhanced osteogenesis remain unknown. Studies have shed some light into what might contribute to this enhanced osteogenesis. RUNX2 has been shown to increase in the presence of macrophages and inflammatory cytokines and this increased expression results in an increase in bone mineralization.¹³⁷ Other studies have demonstrated an increase in the tumor necrosis factor family and ILs, including IL-1, IL6, IL-8, IL-10, IL12, and IL-18.¹³⁹

The most recent work in this field has focused on BMP signaling as a central mechanism that leads to ectopic bone formation. Early studies demonstrated that inhibition of transcriptional activity of BMP type I receptors with antagonists such as noggin and chordin has been shown to disrupt the osteoblast differentiation signaling pathways.^{139,140} Mice lacking noggin showed overactivity of BMP and displayed HO. The role of BMP signaling as an important regulator of ectopic bone formation, along with other mediators such as PDGF, insulin-like growth factor 1 (IGF-1), and TGF-beta1, continues to be the focus of research. Identifying pharmacologic therapies that inhibit the overactive inflammatory response may inhibit the development of HO.¹⁴¹

Additional studies have focused on the identification of progenitor cells responsible for HO. Nesti et al.¹⁴⁰ identified and isolated a population of multilineage mesenchymal stem cells with osteogenic potential that were localized primarily in traumatized tissue. Mesenchymal stem cells are multipotent, adult progenitor cells of great interest because of their unique immunologic properties and regenerative potential.¹⁴² These progenitor cells have been shown to promote wound healing and regeneration of surround tissues by migrating to the site of injury, promoting repair and regeneration of damaged tissue, modulate the immune and inflammatory response, and secrete trophic factors that are important in wound healing and tissue remodeling.¹⁴²⁻¹⁴⁶ Tissue resident progenitor cells are known to be highly sensitive to the surrounding inflammatory milieu.^{147,148} Interestingly, a study by Wu et al.¹⁴⁹ indicates that exposure of skeletal muscle satellite cells to the serum of burned rats is sufficient to promote their osteogenic differentiation, suggesting that both systemic and local inflammations may play a role in driving stem cell differentiation. In addition, studies have recently shown that burn injury promotes HO of adipose-derived stem cells in a murine model of scald injury. Microcomputed tomography and histologic analysis demonstrated increased endochondral ossification in the burn group compared to the sham control, a process which was most likely mediated through increased vascularization.¹⁵⁰ While resident mesenchymal stem cells seem to be implicated in the pathogenesis of HO, there is reason to believe that the immunomodulatory properties of these cells may be activated to suppress the proinflammatory microenvironment when applied externally.¹⁵¹ Further studies are necessary to fully elucidate the therapeutic utility of these cells.

Other groups have shown that these mesenchymal progenitor cells can be isolated from both health and traumatized muscles. Both health and traumatized muscles have osteoprogenitor cells that have the potential to form ectopic bone after injury.¹⁴⁰ Laboratories have suggested that cells responsible for HO are from the endothelium of the local vasculature.¹⁵² These studies suggest that in a setting of chronically stimulated BMP activity, muscle injury and associated inflammation sufficiently trigger heterotopic bone formation and that cells of vascular origin are essential to the development of ectopic bone. This cell lineage, along with stimulating factors such as BMP that create the correct environment for bone formation, could be target for the development of therapeutic interventions to treat HO.¹⁵³ Further understanding the signaling pathways and the involvement of MSC differentiation is essential for the development of early diagnostic and prognostic tests and the development of novel prophylactic therapies.

REHABILITATION

In addition to an increased need for reconstructive surgery secondary to increased survival, there is also an increased need to focus on functional, social, and psychological rehabilitation. The National Institute of Disability and Rehabilitation Research (NIDRR) has continued to fund multi-institutional research to better understand long-term rehabilitative outcomes and needs. Therapists must play an integral role of inpatient and follow-up care. Inpatient care should include aggressive splinting and range of motion. As patients transition to discharge, therapists should work on strengthening, performing activities of daily

living, and occupational guidance.

NONBURN CONDITIONS COMMONLY CARED FOR IN BURN CENTERS

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis syndrome (TENS) have widespread necrosis of the superficial portion of the epidermis (Fig. 12-14). SJS/TEN is commonly associated with sulfonamides, trimethoprim-sulfamethoxazole, oxican NSAIDs, chlormezanone, and carbamazepine. However, a single offending drug is identified in less than 50% of cases. Antibiotic-associated SJS/TEN presents ~7 days after drug is first taken whereas anticonvulsant-associated SJS/TES can present up to 2 months after drug is first taken. TEN can also be caused by staphylococcal infections in immunocompromised patients. In general SJS total involvement is defined as less than 10% TBSA with widespread erythematous or purpuric macules or flat atypical targets are present. TEN has total cutaneous involvement of greater than 30% TBSA and SJS-TENS overlap involves 10% to 30%. Given the difficulty distinguishing these from drug eruptions we recommend a biopsy be sent. This biopsy is also crucial for treatment as steroids are often recommended for drug eruptions but they have not been shown to improve outcomes in patients with SJS and TENS. It is crucial in these patients to assess the oral, ophthalmologic, and urogenital mucosa. Oral mucosal involvement can create a difficult airway as the difficult airway team should be present if intubation is necessary. We recommend aggressive lubrication of the periorbita and an ophthalmology consult if the eyes are involved and OB/Gyn should be consulted for vaginal mucosal involvement. Treatment of the skin sloughing should include a nonstick silver impregnated gauze. If large skin involvement we typically use acticoat. Some centers, however, have demonstrated success with xenograft treatment of large open areas. Currently the data do not support steroid or intravenous immunoglobulin (IVIG) treatment.

Figure 12-14. Stevens–Johnson syndrome and toxic epidermal necrolysis syndrome.

Figure 12-15. Ischemia of the extremities leading to amputation.

Staph scalded skin syndrome has a similar skin appearance to TENS except that it also has positive blood cultures. These wounds are usually more superficial than TEN and the mucosa and conjunctiva are typically not involved. Patients should receive empiric and subsequently culture-based antistaphylococcal antibiotics.

Purpura fulminans often presents after streptococcal or meningococcal sepsis. These patients often have multisystem organ failure secondary to septic shock and vasopressive treatments for cardiovascular support. Patients often suffer from ischemia of the extremities. Treatment of the wounds should be supportive until the patient is stable enough for a definitive operation. Given that tissue death occurs from ischemia, these patients often require amputations ([Fig. 12-15](#)).

CONCLUSION

Burns are responsible for significant morbidity and mortality and are among the most complex and devastating of all traumatic injuries. Early proper diagnosis of burn depth and extent allows for the delivery of appropriate treatment ensures the best prognosis for burn patients. Early tangential excision and autografting remain the foundation of burn treatment. New technologies have advanced the method of diagnosis from punch biopsies to less invasive imaging studies. Diagnosis of secondary burn complications, such as joint contracture and HO, has also advanced with new imaging tools, such as the Raman spectroscopy, that may allow for earlier detection and treatment of ectopic bone formation. The management of burn patients requires a team of physicians, nurses, critical care specialists, physical therapists, and counselor to provide optimal care to patients and lessen the burden of the initial burn injury. Novel clinical, basic science, and translational science researches continue to improve our understanding of the pathophysiology of burn injuries. By elucidating the pathophysiology of both the primary wound and secondary complications will assist in the treatment during the critical period and following the initial trauma and prevent secondary burn complications.

Chapter 13

Anesthesiology and Pain Management

Sachin Kheterpal and Michael R. Mathis

Key Points

- 1 Anesthetics are generalized depressants of consciousness, pain, cardiopulmonary function, motor function, and recall.
- 2 To prevent movement and to facilitate the surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction.
- 3 Residual neuromuscular blockade is a common and underappreciated phenomenon that impacts postoperative adverse events such as hypoxemia, pneumonia, reintubation, and prolonged recovery room stay. Suggamadex, a novel medication capable of reversing deep neuromuscular blockade, may revolutionize perioperative care for high-risk patients.
- 4 Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties.
- 5 Propofol is unique because it is rapidly cleared through hepatic metabolism to inactive metabolites in a way that the patient becomes alert soon after cessation of the infusion. However, as the duration and dose of the maintenance infusion is increased, the time to return of consciousness is also significantly increased.
- 6 Although neuraxial techniques may decrease pulmonary complications, they are associated with hemodynamic instability and are contraindicated in patients with severe flow-dependent cardiovascular diseases.
- 7 Peripheral nerve blockade can be used in lieu of general anesthesia as a primary anesthetic for surgery, or in conjunction with general anesthesia to serve as a postoperative pain management technique. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief.
- 8 The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway can be secured via intubation, the patient must be supported through mask ventilation. The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability.
- 9 Laryngeal mask airways offer an alternative to endotracheal intubation for general anesthesia airway management in selected patients and procedures.
- 10 More than 8% of patients undergoing major noncardiac surgery will experience postoperative myocardial ischemia, elevating their risk of 30-day mortality. Benefits must be weighed against risk of initiating preoperative beta-blockers, alpha-blockers, and aspirin.
- 11 The appropriate duration to defer elective surgery after coronary stenting remains controversial, but recent guidelines from the American College of Cardiology/American Heart Association recommend 365 days for drug-eluting stents and 30 days for bare-metal stents. The role for antiplatelet therapy remains a major question, but data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major improvement in bleeding adverse events.
- 12 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that the patient's chronic disease is under appropriate medical therapy before an elective procedure; and (c) to gain rapport with and the confidence of the patient, answer any questions, and allay fears.
- 13 Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period and should be immediately

referred to their primary care physician and an anesthesiologist to create a pain management plan prior to the day of surgery. Buprenorphine is mixed opioid agonist/antagonist that tightly binds at the μ -receptor and has a long and varied half-life (24 to 60 hours). It can inhibit the analgesic benefits of traditional opioids in the postoperative period, resulting in uncontrolled pain, decreased patient satisfaction, and the potential for adverse events due to the need for very high doses of opioids.

- 14 As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of systolic pressure variation (SPV) is inversely related to the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg. Other measures such as pulse pressure variation (PPV) use similar physiologic assumptions to assess volume status.
 - 15 Enhanced recovery programs incorporating preoperative optimization, standardized surgical and anesthesia protocols, and goal directed therapy may improve patient outcomes and reduce costs.
 - 16 Postoperative acute pain management may require a multimodal approach that incorporates opioids, peripheral nerve blockade, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization by an anesthesiologist.
-

The goal of intraoperative anesthesiology interventions is to enable the safe conduct of otherwise painful interventional procedures with maintenance of patient cardiopulmonary, renal, and neurologic homeostasis while optimizing procedural conditions. The state of general anesthesia is a combination of hypnosis, amnesia, analgesia, and muscle relaxation. This state can be achieved by administration of single or multiple anesthetic agents via inhalational or intravenous routes. Historically, anesthesia was achieved by inhaling volatile anesthetic vapors that produced each of these conditions in proportion to the concentration achieved in the central nervous system. Anesthesia can also be achieved by using a balance of multiple pharmacologic agents, each targeted to produce a specific effect. These are the hypnotic/sedatives, analgesics, and neuromuscular blocking agents. As the concentration of hypnotic/sedative and analgesic agents increases, cardiovascular and respiratory functions may be progressively blunted. For this reason, modern anesthetics usually require titration of these agents to optimize conditions for the surgery while maintaining cardiovascular stability.

Surgical anesthesia is administered with a high degree of safety 30 to 40 million times a year in the United States, despite the serious potential complications of technical or judgment errors. The high degree of success of both surgical and anesthetic outcomes is due to the efforts of thousands of surgeons and anesthesiologists who have advanced the art and science of their field.¹ Although modern surgical techniques, regional or neuraxial blockade procedures, and systemic analgesics have made it possible to ameliorate perioperative pain, significant challenges in postoperative pain management remain. Pain not only is unpleasant, but also can provoke a stress response within the body, leading to significant adverse physiologic effects.

ANESTHETIC AGENTS AND THEIR PHYSIOLOGIC EFFECTS

Inhalation Agents

1 Anesthetics are generalized depressants of consciousness, pain, cardiopulmonary function, motor function, and recall. The potent inhalation agents (e.g., isoflurane, sevoflurane, desflurane) produce these effects in a dose-dependent fashion. The measurement used to compare the potency of inhalation agents is the minimum alveolar concentration (MAC), an empirically derived number defined as the expired percent concentration required to prevent movement on painful stimulation (incision) in half of experimental subjects. There is significant patient-to-patient variability independent of underlying comorbidities. Compounding this variability are the effects of age, weight, pre-existing heart disease, liver disease, and medications other than the inhalational anesthetic. Table 13-1 lists the modern commonly used inhalation agents and their MACs and side effects. In general, all agents depress blood pressure by myocardial depression and vasodilation, resulting in systemic hypotension. There is a generalized depression of cerebral function and cerebral metabolic rate of oxygen consumption, although cerebral blood flow may increase because of cerebrovascular dilatation and a loss of flow-metabolism coupling. Renal blood flow and glomerular filtration rate are reduced by 20% to 50%. The

body’s normally tight regulation of core body temperature is lost, resulting in a redistribution of heat from the core to the periphery. The combination of these effects, the cold environment of the operating room, and open body cavities make the patient extremely vulnerable to hypothermia (core body temperature < 36°C).

Intravenous Sedatives/Hypnotics

Several commonly used intravenous sedative/hypnotic medications can also be used in lieu of an inhalational anesthetic to achieve the hypnotic component of the state of anesthesia. A constant intravenous infusion of these medications is used to achieve and maintain a blood concentration that results in the loss of consciousness and prevents recall. Unlike the inhalational agents, currently, there is no ability to measure the patient’s expired or blood concentration of these intravenous agents. As a result, the infusion rate is titrated to effect by observing patient movement (if muscle relaxants are not used concurrently) and hemodynamic responses to procedural stimuli. Of note, the sedative/hypnotic intravenous agents do not possess clinically useful muscle relaxant or analgesic properties and must be combined with other agents to deliver a “balanced” anesthetic. The most commonly used intravenous agent for maintenance of anesthesia is propofol, a lipid-soluble substituted isopropyl phenol, that produces hypnosis and sedation through interactions with Γ -aminobutyric acid (GABA), the primary inhibitory neurotransmitter of the central nervous system. When administered as a continuous infusion, propofol can achieve minimal levels of sedation, deep sedation, or general anesthesia. Additional details regarding the use and side effects of propofol are discussed later. Other classic agents such as benzodiazepines can also be used as maintenance infusions, but do not enable the rapid return to consciousness that propofol offers. A novel, highly specific α_2 -receptor agonist, dexmedetomidine, has recently demonstrated an exciting role as an intravenous sedative/hypnotic that also has analgesic effects and a lack of respiratory depression. In the perioperative setting, it is currently limited to use as an adjunct to propofol and inhalational anesthetics for general anesthesia or as a sole agent during procedural sedation.

Table 13-1 Common Inhalation Agents: Minimum Alveolar Concentrations and Effects

Agent	Minimum Alveolar Concentration (%)	Strengths	Weaknesses
Nitrous oxide	105	Analgesia Rapid uptake and elimination Less cardiac or respiratory depression	Sympathetic stimulation Expansion of closed air spaces Interference with vitamin B ₁₂ metabolism Limitation of inspired oxygen fraction
Isoflurane	1.15	Good muscle relaxation Stable cardiac rate and rhythm Usability in neurosurgery	Airway irritant, may cause coughing
Desflurane	6	Rapid induction and emergence	Airway irritant, may cause coughing High vapor pressure (Boiling point 23.5°C) requiring special pressurized vaporizer High cost
Sevoflurane	1.71	Rapid induction and emergence Less pungent, does not cause airway irritation	Moderate cost

Muscle Relaxants

2 To prevent movement and to facilitate the surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction. The only noncompetitive inhibitor used clinically is succinylcholine. This drug rapidly binds to the nicotinic receptors and produces depolarization at the neuromuscular junction, clinically manifesting as fine-muscle fasciculations occurring about 30 to 60 seconds after injection. Succinylcholine cannot be reversed, but has a short duration of action (<10 minutes) because it is quickly hydrolyzed in the plasma by cholinesterase. Because of rapid onset and short duration of action, succinylcholine is frequently used to facilitate endotracheal intubation when it must be accomplished quickly, or when quickly regaining neuromuscular function is beneficial.

All other clinically useful muscle relaxants are termed *competitive inhibitors* and do not cause depolarization when they attach at the neuromuscular junction (nondepolarizing). Because these agents

compete with endogenous acetylcholine, the block produced is in direct proportion to the concentration of the agent relative to the concentration of acetylcholine. If the concentration ratio is low enough, competitive relaxants can be reversed if the concentration of acetylcholine is artificially elevated. Acetylcholine concentration can be increased by giving a drug that blocks its metabolism, an anticholinesterase (e.g., neostigmine). The neuromuscular blocking agent is still present, but motor function returns if the acetylcholine concentration is high enough to overwhelm the blocking agent. There is a ceiling to which anticholinesterase drugs can safely elevate circulating acetylcholine; above this threshold, a novel selective relaxant binding agent, sugammadex, may be used to reverse the effects of specific nondepolarizing neuromuscular blocking drugs (rocuronium and vecuronium). Using anticholinesterases to reverse neuromuscular relaxants is not analogous to using naloxone to reverse the effects of opioids. The reversal agent neostigmine does not compete or combine with the relaxant.

Unfortunately, there are systemic consequences to increasing the plasma concentration of acetylcholine. Acetylcholine is the predominant neurotransmitter in the preganglionic sympathetic and parasympathetic nervous systems and in the postganglionic parasympathetic nervous system. For this reason, an anticholinergic drug (atropine or glycopyrrolate) must be given with the anticholinesterase to prevent the undesirable effects of a generalized acetylcholine overdose. Given these side effect profiles of anticholinesterase drugs, the selective relaxant binding agent sugammadex – recently approved for use in the US – offers new promise for reversing high levels neuromuscular blockade. The common neuromuscular blocking drugs and their doses, durations, and side effects are listed in [Table 13-2](#); common regimens of reversal agents are shown in [Table 13-3](#).

3 Postoperative residual neuromuscular blockade is now recognized as a common problem after routine administration of nondepolarizing muscle relaxants. The evaluation of depth of muscle relaxation is a subjective process based upon empirical pharmacokinetics or visual inspection of a patient's peripheral nerve response to an artificial electrical stimulation. During peripheral nerve stimulator monitoring, two electrode patches are placed on the patient's skin along the course of a peripheral nerve which innervates a distinct and observable muscle group. Commonly used monitoring locations include the ulnar nerve, ophthalmic branch of the facial nerve, or the posterior tibial nerve. Next, the electrodes are connected to a hand-held device which delivers four short transcutaneous bursts of electricity, ranging from 10 to 100 mA every 0.5 seconds, hence the term "train-of-four monitoring." A clinician visually inspects the response to each electrical stimulation. In a patient without any pharmacologic neuromuscular blockade, the strength of the fourth muscle response (or "twitch") matches that of the first. In the face of complete pharmacologic competitive inhibition of neuromuscular transmission, no muscular twitches are observed at all. At varying levels of neuromuscular blockade in between, the fourth, third, or second twitch may be absent. Due to competitive blocking of the neuromuscular junction nicotinic receptor, each incremental stimulation results in a weaker response because of increasingly limited receptors available for stimulation. The ratio between the strength of the fourth twitch and the first twitch is known as the train-of-four ratio. During normal neuromuscular transmission, the ratio is 1. Historically, a ratio of 0.7 was considered adequate muscular strength for extubation. However, more recent literature suggests that a ratio between 0.7 and 0.9 still exposes the patient to significant risks of atelectasis, hypoxemia, aspiration, pneumonia, and possibly reintubation. In routine practice, a clinician is incapable of assessing a concept as precise or nuanced as train-of-four ratio. As a result, the number of twitches observed is typically reported, that is, 0/4, 1/4, 2/4, 3/4, 4/4. A patient with 3/4 or 4/4 twitches is capable of responding to cholinesterase inhibitors and return to normal function. A patient with 0/4, 1/4, or 2/4 is unlikely to respond to cholinesterase inhibitors with full return of muscular strength. Data from multiple centers have demonstrated that a significant proportion of patients demonstrated residual neuromuscular blockade of <0.9 in the recovery room despite reversal.

Table 13-2 Common Neuromuscular Blocking Drugs and Reversal Agents

Muscle Relaxant	Intubating Dose (mg/kg)	Infusion Dose (mg/kg/min)	Strengths	Weaknesses
Depolarizing				
Succinylcholine	1.0	100 ^a	Fastest onset (30–60 s) Short duration ^b (5–10 min)	Associated with malignant hyperthermia, dysrhythmias, bradycardia, and hyperkalemia, especially in patients with burns or neurologic injury
Nondepolarizing				
Cisatracurium	0.2	0.1	Spontaneous degradation, not affected by renal or liver disease	Moderate cost
Vecuronium	0.1	1	No cardiovascular effects	
Rocuronium	0.8	10	Fast onset, no cardiovascular effects	

^aThis should not be used for longer than 1 h.

^bDuration is dramatically increased in patients with abnormal plasma pseudocholinesterase.

Table 13-3 Drugs for Antagonizing Nondepolarizing Neuromuscular Blockade^a

Dose	Time to Peak Effect (min)	Dose	Use With	Comments
Anticholinesterases				
Edrophonium	1–2	0.5–1.0 mg/kg	Atropine	Very fast onset, not commonly used
Neostigmine	3–5	0.04–0.07 mg/kg	Glycopyrrolate	Most commonly used
Pyridostigmine	10–12	0.2–0.3 mg/kg	—	Not used clinically for neuromuscular reversal
Selective Relaxant Binding Agents				
Suggamadex	2–3	4.0 mg/kg	—	Primarily used for reversal of rocuronium and vecuronium

CNS, central nervous system.

^aFor reliable results in reversing the effects of nondepolarizing muscle relaxants, administration of anticholinesterases is delayed until spontaneous recovery permits three of four responses to a train-of-four stimulus. For patients with more profound blockade, larger amounts of anticholinesterases may be required, but doses of neostigmine higher than 0.14 mg/kg are unlikely to produce additional improvement. Adapted from Watling SM, Dasta JF. Prolonged paralysis in intensive care unit patients after the use of neuromuscular blocking agents: a review of the literature. *Crit Care Med* 1994;22:884.

The use of subjective train-of-four monitor is inferior to objective acceleromyography, a calibrated device used to accurately establish the train-of-four ratio. It requires careful calibration and setup, and access to the patient's arm and hand. Although clinically effective at eliminating the limitations of subjective train-of-four monitoring, its use remains limited because of the time spent in set up, and an underappreciation of the frequency of residual neuromuscular blockade. It has been promoted by patient safety experts, and is beginning to demonstrate increased penetration in Europe.

In addition to the limitations intrinsic to nerve monitoring devices themselves, nerve monitoring must be performed with caution, as muscles in the body are not equally sensitive to muscle relaxants. The diaphragm is most resistant to neuromuscular blockade, whereas the neck and pharyngeal muscles that support the airway are most sensitive. It is possible for an intubated patient to spontaneously ventilate and even to produce a large negative inspiratory effort and yet develop complete airway obstruction when extubated because of the effects of residual muscle relaxant on the upper airway muscles.

As described earlier, a novel class of compounds known as *selective relaxant binding agents*, – currently comprised of only one FDA-approved drug, suggamadex – may serve to revolutionize the practice of neuromuscular blockade and its reversal. Such compounds are able to rapidly reverse the effects of profound levels of muscle relaxation (0/4 twitches) created by steroidal nondepolarizing muscle relaxant agents such as rocuronium, vecuronium, or pancuronium. Rather than attempting to increase the concentration of acetylcholine, these agents physically bind free muscle relaxant molecules within a cyclodextrin ring structure. This decreases the concentration of free muscle relaxant and allows acetylcholine to function normally at the neuromuscular junction. The cyclodextrin–muscle relaxant combination is then eliminated via the kidney. This offers the ability to rapidly (<3 minutes) reverse profound muscle relaxation as surgical conditions warrant.² This will enable profound relaxation during wound closure, and then immediate reversal of blockade just prior to extubation. Its significant expense, approximately \$US 200 for a single dose of reversal of deep blockade, has limited its use.

Opioids (Narcotics) and Other Intravenous Analgesics

4 Narcotics and synthetic analogues belong to the class of drugs called *opioids*. The most commonly used drugs in this family are morphine, fentanyl, and hydromorphone. Since the mid-1980s, a series of synthetic opioids have been developed with fentanyl as the prototype. More recently developed

synthetics (sufentanil, alfentanil, and remifentanil) are more potent and of varying duration (Table 13-4). Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties. Opioids can produce significant hemodynamic effects indirectly by releasing histamine or blunting the patient’s sympathetic vascular tone because of analgesic properties. The latter effect depends on the degree of sympathetic tone that is present at baseline. Acutely injured patients may be hypovolemic and in pain, with high sympathetic tone and peripheral vascular resistance. Patients in this condition can experience dramatic drops in systemic blood pressure with minimal doses of opioids. For this reason, it is important to titrate narcotics in small incremental doses. Because of the lack of direct myocardial depression and the absence of histamine release with the synthetic opioids, they are frequently used as the primary anesthetic in combination with an amnesic agent and a muscle relaxant in patients with significant myocardial dysfunction.

When opioids are titrated intravenously, patients first become apneic because of the respiratory depressive effect (shifting the CO₂ response curve), but they still breathe on command. As the dose increases, patients become apneic and unresponsive.

Opioids are primarily analgesic and not amnesic. Patients can be totally aware and have substantial recall of conversations despite appearing completely anesthetized. All opioids can be reversed with naloxone. The duration of action of naloxone can be shorter than that of the opioid, and patients must be observed carefully for renarcotization after they have been treated with naloxone. Naloxone reversal of opioids can be dangerous because the agent acutely reverses not only the analgesic effects of the opioid but also the analgesic effects of native endorphins. Naloxone treatment has been associated with acute pulmonary edema and myocardial ischemia and should not be used electively to reverse the effects of a narcotic. It is appropriately used in an emergency situation when the airway is poorly controlled and the patient is not ventilating because of an opioid overdose.

Table 13-4 Analgesics

	Potency	Sedation Dose	Duration	Infusion Dose
Opioids				
Morphine	1	0.02–0.1 mg/kg IV	2–7 h	—
Fentanyl	100	0.5–1 mcg/kg IV	30–60 min	—
Sufentanil	1,000	Not recommended	—	—
Alfentanil	25	10–20 mg/kg IV	10–15 min	—
Remifentanil ^a	—	Not recommended	10 min	0.1–0.2 mg/kg/min
Other Analgesics and Anesthetics				
Propofol		0.1–0.5 mg/kg IV ^{b,c}		100–200 mcg/kg/min ^b
Ketamine		0.1–0.5 mg/kg IV ^b 1.0–2.0 mg/kg IM		1–2 mg/min (anesthetic dose) 500 mcg/kg (analgesic dose)
Dexmedetomidine		Not recommended		0.2–1.0 µg/kg/h

IM, intramuscular; IV, intravenous.
^aWill produce apnea.
^bMay produce apnea.
^cProduces pain on injection that can be reduced by treatment with 20 mg of lidocaine IV.

Propofol

5 Propofol is a lipid-soluble substituted isopropyl phenol that produces a rapid induction of anesthesia in 30 seconds followed by awakening in 4 to 8 minutes after a single bolus. Intravenous propofol can effectively produce total anesthesia (for less stimulating procedures), including amnesia, some analgesia, and some degree of muscle relaxation. Propofol is unique because it is rapidly cleared through hepatic metabolism to inactive metabolites in a way that the patient becomes alert soon after cessation of the infusion. However, as the duration and dose of the maintenance infusion is increased, the time to return to consciousness is also significantly increased. This context-sensitive half-life of propofol must be incorporated into expectations of a “quick wake-up.” Propofol has direct antiemetic properties and is a valid alternative to inhalational anesthetics in patients who have demonstrated a history of prolonged, refractory postoperative nausea and vomiting. It has an important role in intensive care units when used as a continuous infusion sedative at dosages of 25 to 50 µg/kg/min. However, prolonged infusions have been associated with a lethal metabolic derangement known as propofol infusion syndrome, characterized by a profound metabolic acidosis and cardiovascular compromise.³ Due to dose-dependent direct myocardial depression and peripheral vasodilation, propofol can produce significant hypotension when IV induction doses are administered. It also produces

significant pain on injection in peripheral veins. Pain can be diminished or eliminated by pretreatment with IV lidocaine via the vein to be used for propofol administration. Propofol is insoluble in aqueous solution and therefore comes dissolved in a lipid emulsion that has the associated risk of bacterial contamination. Once a vial of propofol is opened, it is not recommended that it be used after 12 hours.

Ketamine

Ketamine is a phencyclidine derivative that produces anesthesia characterized by dissociation between the thalamus and limbic systems. Induction of anesthesia is achieved within 60 seconds after IV injection of 1 to 2 mg/kg or within 2 to 4 minutes of intramuscular (IM) injection of 5 to 10 mg/kg. Patients appear to be in a cataleptic state in which their eyes remain open with a slow nystagmic gaze. The drug produces intense amnesia and analgesia but has been associated with unpleasant visual and auditory hallucinations that can progress to delirium. The incidence of these problems can be significantly reduced if benzodiazepines are also administered with the drug. At low doses (0.1 to 0.2 mg/kg IV or 2 mg/kg IM), patients continue to spontaneously ventilate, but cannot be expected to protect the airway should vomiting occur. At higher doses, ketamine acts as a respiratory depressant and produces complete apnea. Ketamine also has direct and indirect sympathetic nervous system stimulatory effects, which can be useful in hypovolemic patients. These effects are diminished or absent in patients who are catecholamine depleted. The sympathetic stimulatory effect increases myocardial oxygen consumption and intracranial pressure, and ketamine is relatively contraindicated in patients with ischemic heart disease or space-occupying intracerebral lesions. Owing to its analgesic properties and relatively preserved respiration, ketamine is frequently used as an IV analgesic during debridement procedures, at doses listed in [Table 13-4](#). IM ketamine (1 to 2 mg/kg) is also very useful for sedating patients who are difficult to manage (e.g., combative or cognitively disabled patient), so IV access can be obtained. Ketamine’s most frequent use is in subanesthetic doses as part of multimodal analgesic regimens hoping to minimize the use of opioids. For procedures requiring general anesthesia that may have significant postoperative opioid requirements, a preincision ketamine bolus dose with a low-dose intraoperative infusion may be associated with improved acute and chronic pain outcomes.⁴

Amnesics and Anxiolytics

Benzodiazepines are the primary class of agents used as amnesics and anxiolytics. The prototype drug, diazepam, has been more recently replaced by its water-soluble analog of shorter duration, midazolam. Lorazepam also belongs in this family of agents, but because it has a very long duration of action, it is not routinely used intraoperatively. Lorazepam has intensive care unit applications ([Table 13-5](#)). Benzodiazepines produce anxiolysis and some degree of amnesia, but have no analgesic properties. Intraoperatively, midazolam is always used in conjunction with an opioid or inhalation agent. Midazolam can be used in combination with the short-acting opioid fentanyl to produce conscious sedation for minor procedures. Benzodiazepines can produce apnea and have synergistic adverse effects with narcotics. Very small doses of midazolam and fentanyl can quickly produce an unconscious apneic patient. As with all anesthetics, benzodiazepines used as IV agents for sedation should be given in small incremental doses to achieve the desired effect. A reversal agent is also available for benzodiazepines (flumazenil). The recommended dosages of these drugs and the reversal agents appear in [Table 13-5](#).

Table 13-5 Anxiolytics and Amnesics (Benzodiazepines)

Name	Dose (mg/kg)	Duration (h)	Strengths	Weaknesses
Midazolam (Versed)	0.05 (infusion dose 0.25 mg/kg/min)	0.5	Water soluble Short duration Good for sedation for short procedures	Acute respiratory depression
Diazepam (Valium)	0.1	1	Intermediate duration	Irritation on IV injection Phlebitis Acute respiratory depression after IV overdose
Lorazepam (Ativan)	0.02–0.08	6–8	Long duration	—
Benzodiazepine Reversal				
Flumazenil (Romazicon)	4–20 (0.2 mg repeated every 2 to 10 min until reversal is achieved) Maximum dose 1 mg	45–90 min	—	May produce seizures, panic, arrhythmias

IV, intravenous.

Local Anesthetics

Local anesthetics constitute a class of drugs that temporarily block nerve conduction by binding to neuronal sodium channels. As the concentration of the local anesthetic increases around the nerve, autonomic transmission will be blocked first, followed by sensory transmission, and then motor nerve transmission. These drugs can be injected locally into tissue to produce a field block, around peripheral nerves to produce a specific dermatomal block, around nerve plexuses to produce a major conductive block, or into the subarachnoid or epidural space to produce extensive neuraxial blockade. All the methods have been used to assist in the provision of an alternative form of balanced anesthesia by supplementing analgesia and muscle relaxation.

Adverse consequences associated with the use of local anesthetics fall into three categories: acute central nervous system toxicity due to excessive plasma concentration, hemodynamic and respiratory consequences due to excessive conduction block of the sympathetic or motor nerves, and allergic reactions. Whenever a local anesthetic is injected, there can be inadvertent intravascular injection or an overdose of the drug because of rapid uptake from the tissues. Overdose can produce seizures, as well as cardiovascular collapse from ensuing arrhythmias. Complications can be minimized by withdrawing before injection to avoid an intravascular injection and limiting dosages to the safe range (Table 13-6).

Table 13-6 Local Anesthetics

	Maximum Single Dose (mg)	Duration (h)	Comments
Amides			
Lidocaine	500	1 ^a	Fast onset
Ropivacaine	200	4–12 ^a	Less cardiac toxicity than bupivacaine
Bupivacaine	200	4–12 ^a	Exaggerated cardiotoxicity with IV injection Slow onset Long duration
Esters^b			
2-Chloroprocaine	1,000	0.5–1 ^a	Fast onset Lowest toxicity, rapid metabolism
Tetracaine	80	0.5–1	Slow onset

IV, intravenous.

^aAddition of 100 µg of epinephrine (0.1 mL of 1:1,000) lowers the toxicity and increases the duration of the local anesthetic.

^bMetabolism to para-aminobenzoic acid may cause allergic reactions.

6 When local anesthetics are administered for a spinal or epidural block, they produce a progressive blockade of the sympathetic nervous system, which produces systemic vasodilation. Sympathetic nerves travel along the thoracolumbar region with the first four thoracic branches, including the cardiac sympathetic accelerators. A sympathetic blockade of this entire region produces a characteristic profound systemic vasodilatation and bradycardia. This condition is referred to as *total sympathectomy*, and the hypotension that ensues is usually below the minimal cerebral perfusion pressure required to maintain consciousness. Affected patients are bradycardic, hypotensive, unconscious, and usually apneic. This disastrous situation is easily remedied if treated quickly with a vasopressor (phenylephrine or ephedrine) and atropine or small doses of epinephrine (increments of 10 µg for an adult). If not treated promptly, the situation proceeds to cardiac arrest. In this emergency situation, the treatment of high doses of epinephrine is 10 to 40 µg/kg, or 1 to 4 mg for an adult. The doses of epinephrine are higher than in a usual cardiac arrest because of the total sympathectomy.⁵ Because the level of sympathetic block is two to six dermatomal levels higher than the sensory block, it is often difficult to obtain a high spinal sensory level without approaching a total sympathectomy. For this reason, spinal or epidural techniques can present a prohibitively high risk in patients with severe flow-dependent cardiovascular disease.

Local anesthetics are chemically divided into two groups: esters and amides. The esters (2-chloroprocaine and tetracaine) produce metabolites that are related to *p*-aminobenzoic acid and have been associated with allergic reactions. Amides (lidocaine and bupivacaine) are rarely associated with allergic reactions. If an allergic reaction does occur, it is most likely due to the preservative (methylparaben) used in multidose vials of lidocaine.

NEURAXIAL BLOCKADE

Although general anesthesia is employed for millions of surgical procedures each year in the United States, many operations can be performed safely using neuraxial blockade. The two primary neuraxial techniques, a “single-shot” spinal and continuous epidural catheter, can be used for lower extremity and lower abdominal procedures. In both techniques, a small dose of local anesthetic is administered near spinal nerve roots in order to temporarily ablate sensory input from the peripheral somatic and visceral structures. In the case of a spinal anesthetic – also known as a subarachnoid block – the intrathecal sac surrounding the cauda equina at vertebral interspace L2-L3 or below is located using a sterile, small-caliber needle (25 gauge typically). Once cerebrospinal fluid is observed in the hub of a needle, 1 to 2 mL of preservative-free local anesthetic (typically bupivacaine or lidocaine) is injected into the intrathecal space. The needle is then completely withdrawn. This local anesthetic serves to directly inactivate efferent and afferent transmission at the nerve roots it comes in contact with. Because local anesthetics are not specific to specific nerve fiber types, blockade of sensory, motor, and sympathetic nerves occurs. The spread of local anesthetic within the subarachnoid space is primarily determined by three factors: (a) the vertebral interspace accessed, (b) the density of the local anesthetic in relation to the density of cerebrospinal fluid (a concept known as *baricity*), and (c) the position of the patient during injection and immediately thereafter. In order to eliminate the risk of needle puncture of the spinal cord, subarachnoid blocks are only performed below L2-L3 in adults and L3-L4 in children. The local anesthetic solution may be combined with vasoconstrictors such as epinephrine or opioids such as fentanyl or morphine in order to increase the density or duration of the sensory blockade. Surgical anesthesia ranging from 1 to 2 hours can be achieved using a subarachnoid block. Because of concerns regarding permanent nerve damage, intrathecal catheters are typically not used.^{6,7} As a result, most subarachnoid blocks are “single-shot” techniques that cannot be redosed.

In the case of epidural techniques, the nerve roots are blocked outside the thecal sac in potential space between the ligamentum flavum and dura mater. This space is accessed sterily using a 19-gauge introducer needle and a loss of resistance technique. Once the space is identified, a 21-gauge catheter is inserted into the space via the introducer needle and the needle is removed. After testing to reduce the likelihood of inadvertent intravascular or intrathecal placement of the catheter, the epidural catheter can be taped in place. Because the epidural catheter can be left in place for several days, redosing is possible. Dilute local anesthetics combined with vasoconstrictors or opioids are the mainstay of epidural therapy. Epidural neuraxial techniques can be used for surgical anesthesia, as an adjunct to general anesthesia, or for postoperative pain relief. Epidural catheters can be placed in the thoracic or lumbar regions because the intrathecal sac is not being accessed; associated dermatomal spread and analgesia is observed. Epidural techniques often fail to result in a dense sacral nerve root blockade, so this may be a poor choice for surgical anesthesia at or below the knee.

PERIPHERAL NERVE BLOCKADE

7 Peripheral nerve blockade (PNB) has been used for surgical anesthesia of the extremities since the days of intravenous regional anesthesia described by Bier in 1908. PNB differs from neuraxial techniques in that it targets peripheral nerves after they have formed from the combinations of nerve roots. Upper extremity, lower extremity, and visceral peripheral nerves are targets of these peripheral nerve blocks. Much like neuraxial blockade, PNB can be used to achieve intraoperative surgical anesthesia, intraoperative analgesia as an adjunct to general anesthesia, or for postoperative analgesia. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief. The effective use of PNB requires excellent communication between the anesthesiologist and surgeon to ensure that the planned surgical procedure site(s) and any other sources of procedural stimulation (e.g., tourniquet) are adequately addressed by the block. A specific preoperative planning discussion to match the planned surgical procedure to a feasible dermatomal distribution of blockade is essential. Even when blockade of a dermatomal distribution specific to a surgical procedure is feasible, a PNB may be contraindicated if a neurologic examination performed at or near the surgical site in the early postoperative period is necessary.

Because of the limited distribution of sympathetic blockade, PNB has a much smaller hemodynamic effect than general or neuraxial anesthesia. In addition, if general or neuraxial anesthesia can be supplanted by a PNB, the residual unwanted side effects of these anesthetics can be avoided, resulting in improved patient satisfaction, improved quality and speed of recovery, and expedited

hospital/procedural center discharge. However, PNB is not without side effects; the impact of phrenic nerve motor blockade associated with specific upper extremity blocks (common with interscalene and rare with supraclavicular) may have significant consequences for patients with underlying pulmonary disease.

Historically, anatomic landmark-based identification of peripheral nerves was complemented by use of electrical stimulator needles with the hope of eliciting specific motor responses confirming correct needle placement. The technical challenges of establishing precise anatomic location percutaneously by assessing patient symptoms in response to electric stimulation of specific muscle groups are significant. Concerns regarding possible intraneural injection or vascular injury persisted for many years. However, modern anesthesia techniques now employ real-time ultrasound guidance of a PNB needle under direct visualization. Vascular structures and nerves are visualized in relation to a PNB needle in order to decrease the likelihood of intravascular or intraneural injection, increase the likelihood of an efficacious block, and minimize the dose of local anesthetic required to achieve an efficacious block. Despite direct visualization using ultrasound, PNB in adults are typically performed in the awake state to minimize the risk of intraneural injection, which may be detected via patient complaint of significant pain upon injection. PNB can be extremely difficult or contraindicated in patients with challenging body habitus, local superficial infection at the site of needle entry, significant coagulopathy, or implants near the area to be visualized or injected.

While PNB targets named major peripheral nerves resulting in both motor and sensory blockade sufficient for surgical anesthesia, field blocks target small cutaneous sensory nerve fibers, used more commonly to achieve moderate sensory blockade for postoperative analgesia. These blocks typically do not achieve sensory blockade sufficient for surgical anesthesia and must be augmented by general anesthesia or deep sedation. Procedures such as transversus abdominis plane (TAP), adductor canal, intercostal nerve, and local infiltration enable postoperative analgesia.

SEDATION ANALGESIA FOR MINOR SURGICAL PROCEDURES

There are a variety of minor surgical procedures that can be accomplished safely and comfortably with anesthesia provided by infiltration of local anesthetics (most commonly 1% lidocaine or 0.25% bupivacaine) and mild sedation/anxiolysis provided by IV agents. All IV benzodiazepines, narcotics, and other IV anesthetics produce apnea if given in a high enough dose. Because there is a substantial patient-to-patient variability in response to a given dose, IV anxiolytics must be given in small incremental doses slowly to achieve a safe sedated state. When attempting to provide appropriate sedation analgesia for a procedure, it is worth noting that inadequate infiltration of local anesthetic cannot be compensated by increased doses of IV sedatives. Such doses of sedatives as well as narcotics cannot overcome the pain associated with a surgical incision; furthermore, if large doses of narcotics are given for this purpose, a patient may quickly become apneic once the surgical stimulus ends. This is due to the fact that duration of the respiratory depression for even short-acting narcotics is much longer than the painful stimulus of the incision. Because of the potentially serious consequences of an apneic episode, the Joint Commission has required that all patients receiving sedation for minor surgical or medical procedures undergo the following⁸:

Figure 13-1. Classification of the patient's upper airway based on the size of the tongue and the pharyngeal structures visible on

mouth opening. Class I, soft palate and anterior/posterior tonsillar pillars, and uvula visible; Class II, tonsillar pillars and part of uvula hidden by base of tongue; Class III, soft and hard palate visible; Class IV, soft palate not visible, only hard palate visible. (Redrawn from Stoelting RK, Miller RD. *Basics of Anesthesia*, 5th ed. New York: Churchill Livingstone; 2007:146.)

Table 13-7 Sedation Scale

Sedation Scale	Description
1	Awake and alert
2	Awake and sedated
3	Asleep but arousable to touch or verbal stimuli
4	Asleep but arousable to painful stimulus
5	Asleep and not arousable to painful stimulus

1. A preprocedure evaluation including an airway examination ([Fig. 13-1](#))
2. Appropriate monitoring: pulse oximetry as a minimum
3. Documentation of the patient’s vital signs and arterial saturation as well as the dose and timing of sedatives provided during the procedure
4. Documentation of a recovery period and a return to a safe recovered state

The preprocedure evaluation should include current medications, coexisting disease, and a brief physical examination including an evaluation of the airway. The most common drug used to provide sedation is midazolam. This is a fast-onset, relatively short-acting benzodiazepine that can be easily titrated to produce a sedated yet cooperative arousable state. It is usually given to adults in incremental doses of 1 mg (0.01 mg/kg in children). Narcotics such as fentanyl even in small doses act synergistically with benzodiazepines to cause a more sedated state with a much higher incidence of apnea. To assess the effect of the drug, a validated sedation scale can be of value. The scale used at the University of Michigan is presented in [Table 13-7](#).⁹

AIRWAY EVALUATION FOR THE NONANESTHESIOLOGIST

8 9 An essential skill for all clinicians is the assessment of a patient’s airway. It is important to determine how difficult it may be to obtain control of the airway if a patient requires ventilatory support. The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway can be secured via intubation, the patient must be supported through mask ventilation.¹⁰ Supraglottic airway devices (laryngeal mask airways) are of additional consideration, used for both definitive airway management as well as a rescue technique for failed mask ventilation or failed intubation. Limitations to supraglottic airway devices, however, include a relative lack of protection from aspiration, as well as a limited ability to provide adequate positive pressure ventilation in patients prone to airway obstruction (e.g. morbidly obese, sleep apnea). The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability ([Table 13-8](#)).¹¹ Despite decades of research, there is no perfect combination of clinical tests to predict difficult intubation. However, the presence of abnormalities in three or more of the aforementioned elements increases the likelihood of a difficult mask ventilation and/or difficult intubation by more than eight-fold.¹¹ In patients with multiple (three or more) airway abnormalities, the presence of a beard is an easily corrected characteristic: the patient should be asked to shave the beard in order to improve the ability to manage the airway. Assessment of oropharyngeal classification is performed by having patients open their mouth and maximally protrude the tongue without phonation. This Mallampati oropharyngeal assessment can be classified depending on whether the uvula can be completely seen (class 1), only partly seen (class 2), or not seen, with the hard and soft palate visible (class 3), or only the hard palate visible (class 4) ([Fig. 13-1](#)).¹²

Table 13-8 Standard Airway Examination for Nonanesthesiologists

Exam Element	Concerning Findings
Body mass index (kg/m ²)	Body mass index ≥ 31
Mouth opening	Interincisor or intergingival distance >3 cm
Mallampati classification	Class III or IV (see Fig. 13-1)
Mandibular protrusion	Inability to protrude lower incisors to meet or extend past upper incisors
Neck anatomy	Radiation changes, or thick obese neck
Cervical spine mobility	Limited extension or possibly unstable cervical spine
Beard	Presence of full beard

RISKS ASSOCIATED WITH ANESTHESIA

Because the entire purpose of surgical anesthesia is to obtund or completely block physiologic protective mechanisms, there is an underlying baseline anesthetic risk even without a surgical procedure. Fortunately, with the advent of newer agents and monitoring techniques, it is estimated that the mortality rate directly attributable to anesthesia alone has decreased from about 1 in 10,000 patients in the 1950s to as low as 1 in 200,000 or less for healthy patients today.¹³ Although a 1 in 200,000 risk of death or serious neurologic impairment may appear small, when dire consequences occur in a young patient undergoing a purely elective procedure, the consequences are devastating for everyone involved. When patients are placed in a condition in which they cannot breathe, there is always the possibility of a technical or judgmental error resulting in hypoxia and brain damage or death. It has been estimated that between 50% and 75% of anesthetic-caused deaths are due to human error and are preventable. Because the consequences of an anesthetic mishap are usually severe, the emotional and financial costs are high.

Historically, the most common problems associated with adverse outcomes were related to the airway and included inadequate ventilation, unrecognized esophageal intubation, unrecognized extubation, and unrecognized disconnection from the ventilator. The incidence of these problems has been significantly reduced by including capnometry and pulse oximetry in addition to other noninvasive monitors, although a cause-and-effect relation has been difficult to prove. Efforts to improve outcome can be approached at three levels: (a) reduction of the incidence of rare but catastrophic anesthetic-related problems, (b) improvement of the care and experience of every patient undergoing anesthesia and surgery, and (c) improvement of the preparation and management of patients with pre-existing medical conditions who have higher morbidity and mortality rates. The first goal has been addressed in part with improved monitoring techniques, standardized anesthesia machine checklists, and anesthesiology training. Others have been advanced by the addition of comprehensive pain management, as discussed later in this chapter. Issues of pre-existing medical disease and how they affect the anesthetic plan are also briefly discussed later in this chapter.

Cardiovascular Diseases

Hypertension

Hypertension is the most common pre-existing medical disease in patients presenting for surgery and is a major risk factor for renal, cerebrovascular, peripheral vascular, and coronary artery diseases, as well as congestive heart failure (CHF). It is particularly associated with lipid disorders, diabetes, and obesity. It is these associated comorbidities that are most likely to lead to morbidity and mortality in the perioperative period, and therefore, the presence of hypertension should prompt the surgeon to review the history and physical examination for them. Hypertensive patients should be treated medically to render them normotensive before elective surgery. For elective surgical procedures, a sufficient period of time preoperatively should be allocated for antihypertensive management, as rapid correction of hypertension immediately prior to surgery is not without risk of comorbidities, including stroke and other end-organ malperfusion. In general, antihypertension medications should be continued throughout the perioperative period. However, patients treated with angiotensin receptor blockers (ARBs), such as valsartan, candesartan, losartan, or angiotensin-converting enzyme inhibitors (ACE-Is), such as lisinopril, captopril, or ramipril, who are exposed to general anesthesia, are at risk for developing profound, refractory intraoperative hypotension. This ACE-I/ARB hypotension has been treated

successfully with terlipressin, vasopressin, and methylene blue.^{14–16} As a result, most medical centers now recommend withholding ACE-Is/ARBs the morning of surgery.^{17,18} Patients on concomitant diuretic therapy are at greatest risk for intraoperative hypotension requiring treatment.^{19,20}

The incidence of hypotension and myocardial ischemia intraoperatively is higher in untreated hypertensive patients than in adequately treated hypertensive patients if the preoperative diastolic pressure is 110 mm Hg or higher.²¹ Inadequately treated hypertensive patients undergoing carotid endarterectomies have an increased incidence of neurologic deficits, and those with a history of prior myocardial infarctions have an increased incidence of reinfarction. Patients commonly have an elevated blood pressure on admission to the hospital. Hypertensive patients can have exaggerated responses to painful stimuli and have a higher incidence of perioperative ischemia.

Coronary Artery Disease

Much of the anesthetic preoperative evaluation has historically been focused on the detection and treatment of coronary artery disease. Coronary artery disease or its risk factors are present in about 30% of patients who undergo major surgery each year.²² It is the leading cause of death in the United States and continues to be a major cause of postoperative morbidity and mortality.²³ The goal of the preoperative cardiac evaluation is to identify patients who are at increased risk of perioperative cardiac morbidity and ensure that their chronic conditions are optimized. Although perioperative cardiac events are the leading cause of death following anesthesia and surgery, it has been difficult to define patient characteristics that accurately predict a high risk of adverse outcome.²⁴ It has been even more difficult to modify that risk effectively.²⁵ Preoperative CHF is clearly a significant risk factor, as is recent myocardial infarction or unstable angina (Table 13-9). Diabetes mellitus (DM), atherosclerotic vascular disease, and hypertension also appear to confer risk, although less than with CHF or unstable angina. Perioperative risk in patients with valvular heart disease varies with the severity of the disease as represented by CHF, pulmonary hypertension, and dysrhythmias. Dysrhythmias are also a concern in the presence of coronary artery disease. Age and stable angina remain controversial as predictors of perioperative risk, with equal numbers of supporting and refuting studies. The value of revascularization remains controversial as well. In patients without significant pulmonary disease, the ability to climb two flights of stairs without stopping or experiencing symptoms of angina or shortness of breath is considered a good practical test of cardiac reserve. Unfortunately, many patients with ischemic heart disease have concomitant pulmonary disease or other medical problems that limit their activity. A history of myocardial infarction is important information. Large retrospective studies have found that the incidence of reinfarction is related to the time elapsed since the previous myocardial infarction.^{26–28} The incidence of reinfarction appears to stabilize at about 6% (50-fold higher than patient without myocardial infarction) after 6 months. The highest rate of reinfarction occurs in the 0- to 3-month period. Mortality from reinfarction, for patients undergoing noncardiac surgery (Table 13-10), has been reported to be between 20% and 50% and usually occurs within the first 48 hours after surgery.

Table 13-9 Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Heart Failure, Death)

Major
Unstable coronary syndromes
Acute or recent MI ^a with evidence of important ischemic risk by clinical symptoms or noninvasive study
Unstable or severe ^b angina (Canadian class III or IV) ^c
Decompensated heart failure
Significant arrhythmias
High-grade atrioventricular block
Symptomatic ventricular arrhythmias in the presence of underlying heart disease
Supraventricular arrhythmias with uncontrolled ventricular rate
Severe valvular disease
Intermediate
Mild angina pectoris (Canadian class I or II)
Previous MI by history or pathologic Q waves
Compensated or prior heart failure
Diabetes mellitus (particularly insulin dependent)
Renal insufficiency
Minor
Advanced age
Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)
Rhythm other than sinus (e.g., atrial fibrillation)
Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
History of stroke
Uncontrolled systemic hypertension

ECG, electrocardiogram; MI, myocardial infarction.

^aThe American College of Cardiology National Database Library defines recent MI as >7 d but ≤1 mo (30 d); acute MI is within 7 d.

^bMay include “stable” angina in patients who are unusually sedentary.

^cFrom Campeau L. Grading of angina pectoris. *Circulation* 1976;54:522.

Table 13-10 Cardiac Risk Stratification for Noncardiac Surgical Procedures

High (reported cardiac risk often >5%) ^a
Emergent major operations, particularly in the elderly
Aortic and other major vascular surgery
Peripheral vascular surgery
Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss
Intermediate (reported cardiac risk generally <5%)
Carotid endarterectomy
Head and neck surgery
Intraperitoneal and intrathoracic surgery
Orthopedic surgery
Prostate surgery
Low ^b (reported cardiac risk generally <1%)
1. Endoscopic procedures
2. Superficial procedures
3. Cataract surgery
4. Breast surgery

^aCombined incidence of cardiac death and nonfatal myocardial infarction.

^bDo not generally require further preoperative cardiac testing.

10 Perioperative cardiac adverse event risk reduction has undergone significant changes over the past decade. Despite these efforts, a large, international prospective study across 15,000 patients demonstrated that more than 8% of patients undergoing major inpatient surgery still experience postoperative myocardial ischemia.²⁹ These patients have significantly increased 30-day mortality, even though only 15% of perioperative ischemic episodes included typical cardiac symptoms. Previous retrospective studies demonstrating value to coronary revascularization spurred aggressive preoperative coronary artery disease identification and management. However, recent data have questioned the value of coronary revascularization among asymptomatic patients in not only the perioperative period, but also in the general medical population.^{30,31} The most recent American College of Cardiology (ACC)/American Heart Association (AHA) guidelines reserve preoperative coronary revascularization for patients demonstrating asymptomatic left main coronary artery disease, three-vessel disease, reduced ejection fraction, unstable angina, or acute myocardial infarction.³² Furthermore, large retrospective and prospective studies have demonstrated that the institution of perioperative beta-blockade also bears significant risks that must be weighed against possible benefits.^{33,34} As a result, the

most recent ACC/AHA guidelines reserve the institution of beta-blocker therapy for only high-risk patients that would warrant blockade independent of the surgical procedure.³² Patients already on beta-blocker therapy should be continued on the therapy throughout the perioperative period.³² The widespread use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, commonly known as statins, for cardiovascular disease and hyperlipidemia has introduced another medication into the surgical preoperative evaluation. Although prospective data establishing the value of instituting preoperative statin therapy are limited, there is general consensus that these medications should not be withdrawn during the perioperative period.³⁵ A large randomized controlled trial evaluating the benefit of other promising agents – clonidine and aspirin – as perioperative optimization standards failed to demonstrate benefit.^{36,37}

All patients in high-risk groups or with a history of ischemic heart disease must be evaluated and properly treated before elective surgery. All elective surgery should be delayed for 6 months after myocardial infarction. If this is not feasible, invasive monitoring should be considered in the perioperative period and intensive postoperative observation should continue for at least 48 hours. The intrusiveness of the surgical procedure also plays a part in the overall risk and need for preoperative workup of heart disease. The AHA has produced and updated an algorithm for the recommended preoperative workup ([Algorithm 13-1](#)).³²

Percutaneous Coronary Intervention With Stenting

11 The widespread use of percutaneous intervention for coronary artery disease via stenting (with or without drug-eluting coating) has introduced a new level of clinical complexity. In-stent thrombosis is a feared complication with profound morbidity and mortality. Given the known proinflammatory and prothrombotic physiologic state induced by acute illness, surgery, and anesthesia, coronary stents may be at elevated risk for thrombosis during the perioperative period. Large retrospective studies have demonstrated that the risk of perioperative in-stent thrombosis is increased if noncardiac surgery is performed soon after percutaneous coronary intervention.^{38,39} The appropriate duration to defer elective surgery after coronary stenting remains controversial, but recent ACC/AHA guidelines recommend 365 days for drug-eluting stents and 30 days for bare-metal stents.³² The role for antiplatelet therapy remains a major question, but data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major improvement in bleeding adverse events.^{38,39} The decision to stop antiplatelet therapy prior to recommended guidelines should be limited to specific procedures that demand a nearly bloodless surgical field or in procedures involving closed spaces incapable of tolerating minor theoretical increases in bleeding (intracranial, minimally invasive spine surgery). Recent data and recommendations in the surgical literature demonstrate that continuation of aspirin therapy throughout the perioperative period in patients with coronary artery stents should be the standard of care.³²

Congestive Heart Failure

CHF has been described as the single most important factor predicting postoperative cardiac morbidity.⁴⁰ All elective surgical procedures should be deferred until heart failure is medically optimized. If surgery cannot be deferred, aggressive perioperative management is warranted with a goal of optimizing cardiac output. In contrast to isolated ischemic heart disease, CHF is more easily diagnosed by history, physical examination, and basic preoperative laboratory workup, including electrocardiography (ECG) and chest radiography. Because patients with left, right, or both left and right ventricular dysfunction are less tolerant of the fluid shifts associated with surgery and the myocardial depression associated with the anesthetic, they constitute the highest-risk group for postoperative complications. Recent data demonstrate that although cardiac complications have historically been the focus of surveillance and prevention, pulmonary and infectious complications may warrant similar attention.⁴¹

Algorithm 13-1. Decision aid for preoperative cardiac evaluation prior to noncardiac surgery. This decision tree for preoperative evaluation takes into account not only the patient's physical status but also the severity of the surgical procedure. ACC, American College of Cardiology; AHA, American Heart Association; LOE, level of evidence.

Pulmonary Disease

Pulmonary disease is classically divided into acute and chronic restrictive and obstructive disease. Restrictive disease is defined by processes that reduce lung volumes, and obstructive disease is characterized by reduced flow rates on pulmonary function tests.

Obstructive diseases are present in patients with forced expiratory volume in 1 second (FEV₁)/forced vital capacity (FVC) ratios of less than 50%. Obstructive pulmonary disease can be either chronic or acute (asthma). In either case, the reversible component of obstruction should be reversed before elective surgery. Patients are maintained on bronchodilator medications, and those with chronic secretions are appropriately hydrated and receive therapy to mobilize secretions. In patients with reactive airway disease, the endotracheal tube can induce severe bronchospasm. Even in patients who are treated well preoperatively, reactive bronchospasm can complicate anesthetic induction and the emergence from anesthesia. Severe bronchospasm is a life-threatening emergency that can be challenging to diagnose and treat. Administration of potent local (albuterol) and systemic (epinephrine) bronchodilators in a timely fashion is essential.

Regional or neuraxial anesthetics can be useful in these patients for peripheral surgery or for procedures that require an anesthetic sensory level below T6. As the sensory and motor levels rise to T6 and above, patients lose significant accessory motor function that can decrease expiratory reserve volume and the ability to cough and clear secretions. Because of tenuous pulmonary status and the high incidence of postoperative pulmonary complications, these high-risk patients should be extubated with caution only when they meet adequate extubation criteria relative to preoperative test data. Changes in pulmonary mechanics and frequency of postoperative pulmonary complications are greatest after upper abdominal surgery. Both vital capacity and functional residual capacity are reduced, reaching lowest levels in the first 24 hours postoperatively. In the high-risk groups, therapy should be directed toward restoring functional residual capacity to preoperative levels. Such therapy improves compliance and gas exchange. Because of the potential adverse effects of systemic narcotics on respiratory drive, the use of epidural narcotics and local anesthetics for postoperative pain control is very popular. These techniques allow the patients to be extubated earlier and, in patients with intrathoracic and upper abdominal

surgery, help restore pulmonary function toward preoperative values.⁴²

Obesity

Obesity causes a host of problems on both sides of the surgical drapes. Obesity is defined as a body mass index (BMI) greater than or equal to 30 kg/m². BMI can be easily calculated by dividing the patient's weight in kilograms by the square of his or her height in meters. The pathophysiologic changes associated with morbid obesity (BMI $\geq$ 40 kg/m²) affect the respiratory, cardiovascular, and gastrointestinal systems. Patients have an external restrictive lung disease that reduces functional residual capacity and worsens with the supine position. Breathing effort increases and ventilation becomes diaphragmatic and position dependent. Increased airway pressures required to maintain adequate ventilation in obese patients predispose this patient group to barotrauma, furthering their risk of pulmonary complications. Obese patients frequently desaturate at night and have a high incidence of sleep apnea. Because of increased blood volume and frequent desaturations, obese patients can develop pulmonary hypertension and right-sided heart failure. Obese individuals have a high incidence of coronary artery disease. Because of size alone, they have increased cardiovascular demands with limited cardiac reserve and exercise tolerance. Obese patients have a high incidence of hiatal hernia and gastroesophageal reflux, increasing the risk for aspiration on induction and emergence from anesthesia. Issues as mundane as venous access can cause significant problems in this patient group.

A significant concern of the anesthesiologist is gaining adequate control of the airway. The combined problems of aspiration risk, rapid desaturation caused by reduced functional residual capacity and increased oxygen demand, and technical difficulties associated with intubation due to anatomic fat deposits make intubation a high-risk procedure. If problems occur, there can be significant technical difficulties in obtaining a rapid cricothyrotomy. For these reasons, a nasal or oral awake intubation can be useful or even imperative. Patients should receive prophylactic administration of H₂-receptor antagonists and a nonparticulate antacid to improve the pH of gastric contents. If intubations are to be done after induction of anesthesia, they should be performed in a rapid sequence using cricoid pressure. To prevent aspiration on emergence, obese patients should be extubated when fully awake, preferably in the sitting position. Regional anesthetics can be very useful when peripheral procedures are planned. Unfortunately, morbidly obese patients can develop pulmonary failure just by lying flat, making it difficult to use epidural or spinal anesthetics for abdominal procedures. Epidural analgesics for postoperative pain management allow earlier extubation and ambulation of these patients.⁴³

Diabetes Mellitus

The incidence of DM is rising, particularly, type 2 DM in the elderly. This is a systemic disorder that has particular relevance for the anesthesiologist and surgeon because of its effect on the vascular, renal, nervous, and immune systems. Patients with DM should be investigated for the presence of concomitant coronary artery disease, peripheral vascular occlusive disease, renal failure, and autonomic and peripheral neuropathy. Problems with cardiovascular instability, fluid balance, and aspiration due to gastroparesis should be expected. In addition, these patients are more prone to infection and have problems with temperature control. The management of the diabetic state in these patients is important and complicated. Hypoglycemia during the anesthetic state is a feared complication because of challenges in prompt diagnosis. Oral hypoglycemic agents such as glipizide should be stopped prior to surgery and hyperglycemic situations treated with short-acting intravenous or subcutaneous insulin during the perioperative period. Insulin-dependent diabetics for same-day admission or outpatient surgery should take one-half of their usual morning dose of long-acting insulin. After the establishment of an IV line, laboratory blood samples are drawn and treatment of hyper- or hypoglycemia is started. Additional insulin is then given according to the results of frequent (every 1 to 2 hours) blood sugar monitoring. Although there are compelling data associating perioperative hyperglycemia with adverse postoperative events, there are no randomized controlled trials demonstrating improved outcomes with aggressive intraoperative hyperglycemia management.⁴⁴ Furthermore, complications from hypoglycemia are arguably greater than those from hyperglycemia, and are more likely as insulin therapy becomes more aggressive during the perioperative period.

Renal Insufficiency and Failure

Because the kidneys play a vital role in metabolic, synthetic, and fluid management homeostasis, renal failure is associated with many effects on the cardiovascular, pulmonary, hematologic, gastrointestinal, and immune system. Pre-existing renal insufficiency is a known risk factor for postoperative myocardial

infarction and renal failure.^{45,46} Optimizing the fluid and metabolic status of a patient in end-stage renal disease is of vital importance. Elective surgery should be delayed until such optimization is performed. In emergent situations, the urgent need for hemodialysis should be considered intraoperatively or postoperatively to avoid life-threatening electrolyte and fluid derangements. Although postoperative renal failure has historically been the focus of cardiac surgery researchers, national data suggest that nearly 15% of patients undergoing general surgery procedures will also experience postoperative acute kidney injury, as defined by a 0.3 mg/dL increase in serum creatinine within seven postoperative days.⁴⁷ Risk factors for postoperative acute kidney injury in patients undergoing general surgery are listed in [Table 13-11](#). These data should be considered during the patient consent process.

Table 13-11 Predictors of Postoperative Acute Kidney Injury After General Surgery Procedures

Age ≥56 y
Male sex
Emergency surgery
Intraperitoneal procedures
Preoperative renal insufficiency (serum creatinine >1.2 mg/dL)
Ascites
Active congestive heart failure
Diabetes mellitus requiring oral hypoglycemic or insulin therapy
Hypertension requiring chronic medication

From Kheterpal S, Tremper K, Heung M, et al. Development and validation of an acute kidney injury risk index for patients undergoing general surgery. *Anesthesiology* 2009;110:505–515.

Obstructive Sleep Apnea

With the rise in obesity prevalence, obstructive sleep apnea (OSA) is emerging as a major comorbidity that has an impact on postoperative outcomes and costs.⁴⁸ The physiologic changes on the upper airway, lungs, pulmonary circulation, heart, and brain are extensive and challenge not only the immediate perioperative period, but also postoperative management.⁴⁹ These patients are prone to airway collapse at induction and emergence, hypoxemia, delayed emergence, respiratory depression, and cardiovascular collapse.⁵⁰ Preliminary data demonstrate increased sensitivity to the effects of opiates as well.⁵¹ Observational data demonstrate a relationship between OSA treatment and a reduction in postoperative complications, but prospective interventional trials have yet to be conducted.^{52,53} Nevertheless, the standard protocol for all preoperative evaluations should be the use of a locally accepted OSA screening tool (STOP-BANG questionnaire, Perioperative Sleep Apnea Prediction score, etc.) and ensuring postoperative access to continuous positive airway pressure therapy for patients currently prescribed such therapy as outpatients. Some undiagnosed or noncompliant patients may require initiation of therapy in the immediate postoperative period and the perioperative resources to fulfill clinical urgency are essential.

RISKS ASSOCIATED WITH REGIONAL TECHNIQUES IN PATIENTS BEING TREATED WITH ANTICOAGULANTS

As the indications for anticoagulant therapy have increased, ranging from drug-eluting stents to atrial fibrillation and venous thromboembolism prophylaxis, the number of patients and types of anticoagulant therapy has continued to increase. In particular, low-molecular-weight heparin (LMWH) and oral direct factor Xa inhibitors are often part of a patient’s pre- or postoperative therapy plan. The use of neuraxial or PNB anesthesia in patients with preoperative anticoagulation requires careful planning and assessment of the risks and benefits of specific anesthetic techniques and withdrawal of anticoagulant therapy. LMWH raises specific concerns of crippling epidural hematoma formation when neuraxial techniques are used. For that reason, the American Society of Regional Anesthesia has published specific guidelines for central conduction block (spinal and epidural anesthesia) to try to minimize the incidence of this devastating complication⁵⁴: In general, LMWH therapy requires coordination of neuraxial administration at least 12 hours after the last dose. Coumadin, clopidogrel, and ticlopidine should be held for at least 5, 7, and 14 days prior to neuraxial techniques, respectively. The absence of any reversal agents or reliable diagnostic testing for oral direct Xa inhibitors requires a

conservative approach of withdrawal of therapy and no data currently exist to establish a specific threshold. Data regarding risks for PNB are even more scarce and local protocols should be established and followed. Unlike neuraxial techniques, the PNB techniques involve more compliant fascial planes that may allow for increased bleeding without compressive injury to nerve structures.

PREOPERATIVE EVALUATION

12 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that the patient's chronic disease is under appropriate medical therapy before an elective procedure; and (c) to gain rapport with and the confidence of the patient, answer any questions, and allay fears.

Optimally, to complete this task, an anesthesiologist would meet every patient before the planned surgical procedure to review the medical history, complete a physical examination, discuss the options and associated anesthetic risks, and develop an anesthetic plan. In the past, this was accomplished when the anesthesiologist visited the patient in the hospital the night before surgery. Currently, it is rare to have patients admitted the night before surgery even before the most comprehensive and complex surgical procedures. The evaluation must still be accomplished, but it must be done on an ambulatory basis, which creates associated logistical problems.

A patient's medical conditions should be optimized before an elective surgical procedure. This optimization is best performed by the primary care physician, with medical specialty consultation, if necessary. The following questions must be answered when evaluating a patient undergoing an elective surgical procedure (Table 13-12). What must be included in the preoperative evaluation? Second, who is involved in this process? When and where are all the steps in this process to be conducted? How should all the information be coordinated so that it is available to the appropriate personnel at the appropriate time? If the procedure is deemed a surgical emergency, the anesthesiologist is responsible for assessing the patient quickly, developing the appropriate anesthetic plan, and proceeding to the operating room as soon as possible. In an emergency situation, the anesthesiologist is not obligated to seek medical consultation to evaluate chronic medical problems because time is essential.

The following steps must be completed before moving the patient into the operating room:

1. A comorbidity-focused history and physical examination
2. Appropriate laboratory studies and medical consultations
3. An anesthesiologist's preoperative evaluation with assignment of an American Society of Anesthesiologists (ASA) physical status
4. Discussion with the patient the options and risks
5. Development and communication of the anesthetic plan to the patient and surgeon
6. Acute optimization of any pertinent medical conditions

Table 13-12 Results Hospital Mortality Rates in Relation to Age, Preoperative Disease, and Surgery

Preoperative Disease and Surgery	Age (y) <50 ^a	Age (y) 50–69 ^a	Age (y) >70 ^a
Chronic heart failure	0.1%/0.5%	0.4%/2%	0.8%/4%
Renal failure	0.2%/1%	0.9%/2%	2%/9%
Abdominal surgery	0.3%/2%	1%/6%	3%/12%
Chronic heart failure and renal failure	0.7%/3%	3%/13%	6%/24%
Chronic heart failure and abdominal surgery	0.9%/4%	4%/17%	7%/30%
Renal failure and abdominal surgery	2%/8%	2%/32%	16%/50%
Chronic heart failure, renal failure, and abdominal surgery	6%/26%	22%/60%	37%/76%

From Pedersen T, Eliassen K, Henriksen E. A prospective study of mortality associated with anesthesia and surgery: risk indicators of mortality in hospitals. *Acta Anaesthesiol Scand* 1990;34:176, with permission.

^aFigures are for elective surgery (first number) and emergency surgery (second number).

The history and physical examination have repeatedly been shown to be the most valuable parts of the preoperative assessment. To enable ideal operative planning and postoperative care, it is the surgeon's responsibility to obtain a basic history that includes current medical conditions, current medication, and previous surgical history. In addition, the anesthesiologist must review previous

anesthetic problems experienced by the patient or blood relatives, the patient’s exercise tolerance, and additional details regarding general medical conditions. This evaluation not only determines the laboratory tests that may be required but also allows for the assignment of ASA physical status (PS) (Table 13-13). The classification serves as a general measure of the patient’s state of well-being, taking into account all problems the patient brings to the operating room, including systemic disturbances caused by the surgical illness. Although studies of anesthetic mortality show a correlation with the PS classification, this categorization does not describe the risk directly. The risk of any operation is determined not only by patient-related factors but also by procedure-specific ones. For patients with complex medical problems, it is frequently helpful to supplement the surgical history and physical examination with a recent assessment by the patient’s primary physician in order to assess the patient’s long-term health trajectory. There are no data demonstrating the value of routine preoperative medical consultation.⁵⁵

The value of preoperative laboratory studies has undergone substantial reevaluation since the mid-1980s. In the past, a surgical procedure was an opportunity to obtain a battery of baseline laboratory tests, even for ASA PS-1 patients. The current thinking is that a laboratory test should not be ordered unless a change in the surgical or anesthetic plan is anticipated. The only preoperative screening test required at the University of Michigan, for instance, is an ECG within a year of the planned surgical procedure for men older than 50 years and women older than 60 years of age. For procedures with significant anticipated blood loss, a type and cross match is ordered, and a preoperative hematocrit is also required. All other tests should have an indication based on history and physical examination. A current strategy for selecting tests indicated by patient history is presented in Table 13-14. Electronic patient questionnaires have also been developed, allowing the appropriate laboratories to be selected based on the patient’s response to questions.⁵⁶

Table 13-13 Physical Status Classification of the American Society of Anesthesiologists

Physical Status Classification	Description
PS-1	A normal, healthy patient
PS-2	A patient with mild systemic disease that results in no functional limitation <i>Examples:</i> Hypertension, diabetes mellitus, chronic bronchitis, morbid obesity, extremes of age
PS-3	A patient with severe systemic disease that results in functional limitation <i>Examples:</i> Poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris, prior myocardial infarction, pulmonary disease that limits activity
PS-4	A patient with severe systemic disease that is a constant threat to life <i>Examples:</i> Congestive heart failure, unstable angina pectoris, advanced pulmonary, renal, or hepatic dysfunction
PS-5	A moribund patient who is not expected to survive without the operation <i>Examples:</i> Ruptured abdominal aneurysm, pulmonary embolus, head injury with increased intra-cranial pressure
PS-6	A declared brain-dead patient whose organs are being removed for donor purposes
Emergency operation (E)	Any patient in whom an emergency operation is required <i>Example:</i> An otherwise healthy 30-year-old woman who requires dilation and curettage for moderate but persistent vaginal bleeding (PS-1E)

Table 13-14 Simplified Strategy for Preoperative Testing

Estimated Energy Requirements for Various Activities			
1 MET ↓ 4 METs	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2 to 3 mph or 3.2 to 4.8 km/h? Do light work around the house like dusting or washing dishes?	4 METs ↓> 10 METs	Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph or 6.4 km/h? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football? Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

MET, metabolic equivalent; mph, miles per hour.

Discussions of the options of anesthetic techniques and anesthetic risks are best performed by the anesthesiologist who will provide the anesthetic. If the surgeon prefers a specific anesthetic technique, this is best communicated directly to the anesthesiologist rather than recommended to the patient. The

development of the anesthetic plan must be determined by the anesthesiologist.

The history, physical examination, and laboratory studies should be performed by the surgeon as soon as the surgical procedure is scheduled. The results of the laboratory studies must be evaluated well in advance of the day of surgery so that positive findings can be attended to in a timely manner. For healthy patients (ASA PS-1 and PS-2), the preoperative anesthetic assessment can be conducted by the anesthesiologist on the day of the procedure. If the patients have complex medical problems (ASA PS-3 or greater) or have significant concerns they want to discuss with an anesthesiologist, they should be evaluated before the day of surgery. Because of the logistical problems of scheduling, most institutions have developed preoperative anesthesia clinics where this process can take place.

13 In addition, the patient's medication regimen should be reviewed to ensure that appropriate medications are continued or discontinued in the days and hours leading up to an elective procedure. In general, diuretics and ACE-I/ARB medications should not be taken the day of surgery. Several important classes of medications should be continued as per the patient's normal regimen: chronic pain therapy (including opioids), beta-blockers, statins, and proton pump inhibitors. The decision regarding anticoagulant therapy is a complex one that must take into account the indication for therapy, the likelihood and impact of surgical bleeding, and the risk of perioperative thrombosis. Insulin and oral hypoglycemic agents should be continued at a reduced dose given the fasting state of the surgical patient. Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period and should be immediately referred to their primary care physician and an anesthesiologist to create a pain management plan prior to the day of surgery. Buprenorphine is mixed opioid agonist/antagonist that tightly binds at the μ receptor and has a long and varied half-life (24 to 60 hours). It can inhibit the analgesic benefits of traditional opioids in the postoperative period, resulting in uncontrolled pain, decreased patient satisfaction, and the potential for adverse events due to the need for very high doses of opioids.⁵⁷ A management protocol used at the University of Michigan is demonstrated in [Algorithm 13-2](#).

An obvious problem that concerns anesthesiologists is the potential of a difficult intubation. This can be assessed as discussed earlier ([Fig. 13-1](#) and [Table 13-18](#)). Even if a patient has no medical problem, the possibility of a difficult airway warrants that the patient be seen preoperatively and evaluated. These patients can always be approached by an awake fiberoptic technique, but this takes planning and can cause a significant delay if there is no prior warning.

MONITORING THE SURGICAL PATIENT

One of the more obvious changes in anesthesia care has been the routine use of an array of electronic monitoring devices to provide continuous surveillance of physiologic status. Because the art and science of anesthesiology involves titrating pharmacologic agents to produce desired physiologic effects, there must be a measured parameter to which drug dosages are titrated. Depending on the severity of pre-existing disease and the extent and duration of the surgical procedure, invasive techniques can be used to provide comprehensive continuous data to guide the titration of fluid therapy and cardiovascular agents.

Monitors of Oxygenation

Pulse oximetry has been called the most significant advance in patient monitoring to date. This device continuously, noninvasively, and inexpensively provides arterial hemoglobin saturation (SaO_2) and peripheral pulse by measuring light absorption in a manner similar to that of a laboratory co-oximeter. A laboratory co-oximeter shines light through a cuvette filled with a blood sample. Each hemoglobin species absorbs light in direct proportion to its concentration (Beer–Lambert law). A cooximeter requires one wavelength of light for each hemoglobin species to be measured, that is, one wavelength for oxyhemoglobin and one for reduced hemoglobin. To measure other hemoglobins, such as carboxyhemoglobin or methemoglobin, the device requires four wavelengths of light.

The traditional pulse oximeter uses two wavelengths of light, one red and one infrared, that shine through a tissue bed, usually a finger. Opposite the light sources is a photodiode that measures the transmitted light intensity. A large proportion of the light absorbed as it passes through the tissues is not associated with arterial blood but with other components of the tissue, such as skin, muscle, bone, and venous blood. Therefore, the device analyzes only the pulsatile component of absorption and

assumes that anything that pulses within the tissue bed is arterial blood, hence the name *pulse oximeter*. Actually, the pulse oximeter measures the ratio of the pulsatile component of red light absorbed to the pulsatile component of the infrared light absorbed. This ratio changes with SaO₂. The exact relation between this ratio and SaO₂ has been empirically determined from volunteer studies and is programmed into the electronics of the oximeter. If any artifacts occur in a pulsatile nature, they may be erroneously integrated into the equation, causing erroneous SaO₂ estimates.

Several things should be remembered when interpreting a pulse oximeter's output. First, the device measures SaO₂ and not arterial oxygen tension (PaO₂). The PaO₂ must drop below 80 mm Hg before any significant change in SaO₂ occurs. As the PaO₂ drops below 60 mm Hg, the SaO₂ rapidly falls as the inflection point of the sigmoidal oxyhemoglobin dissociation curve is approached. As a rough rule of thumb, as SaO₂ drops below 90%, the PaO₂ can be estimated by subtracting 30 points from the SaO₂. For example, a SaO₂ of 85% corresponds to a PaO₂ of 55 mm Hg. Second, the pulse oximeter measures saturation (milliliters of oxygen per deciliters of blood) and not arterial content or oxygen delivery to tissues.

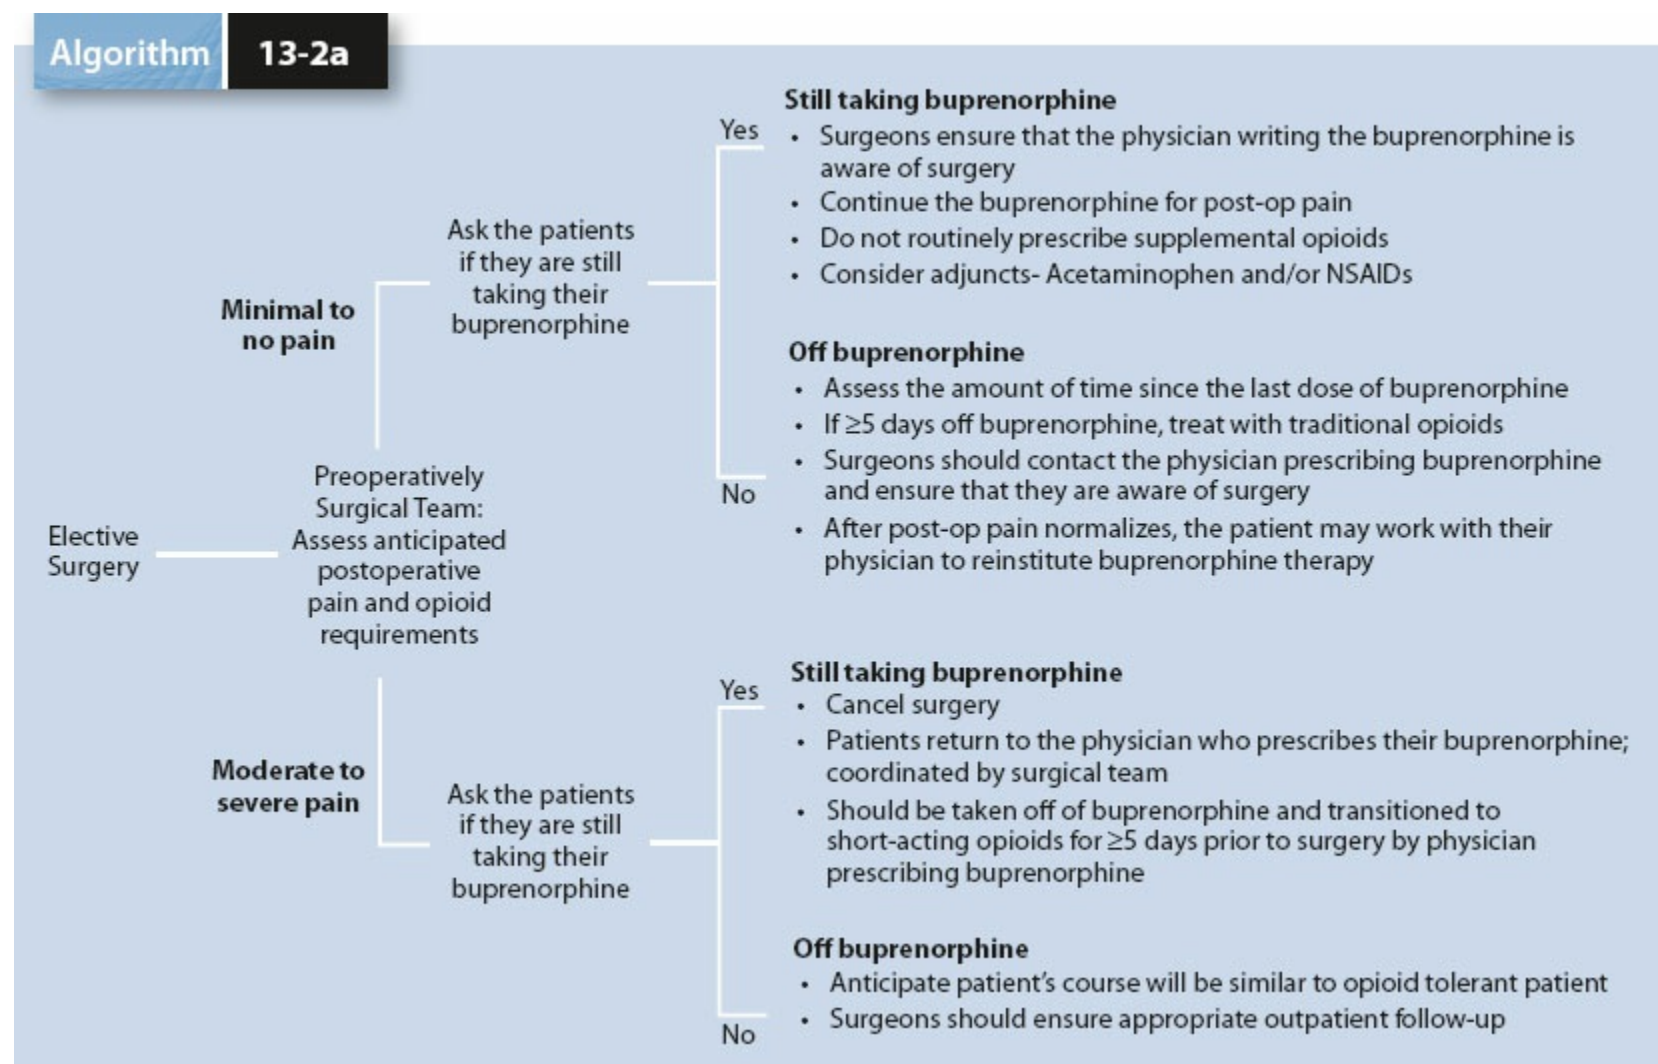

Because a traditional pulse oximeter uses only two wavelengths of light, it cannot detect the presence of carboxyhemoglobin (carbon monoxide poisoning) or methemoglobin. Recently introduced pulse oximeters incorporate additional wavelengths of light and are capable of detecting carboxyhemoglobin and methemoglobin ratios as well.⁵⁸ In addition, continuous measurement of hemoglobin (mg/dL) via certain pulse oximeters allows the trending of intraoperative hemoglobin during procedures involving moderate to large blood loss, guiding transfusion therapy. Although the margin of measurement error is as large as 1 mg/dL when compared to central laboratory complete blood counts, the data do offer a trend and may reduce unnecessary transfusions in clinical settings without access to point of care blood gas machines.

Ventilation Monitors

By definition, a patient is appropriately ventilated when arterial carbon dioxide tension (PaCO₂) is 40 mm Hg. Measuring the respiratory rate can document only the presence of ventilation, not its adequacy. Capnography, or end-tidal CO₂ monitoring, is the visual display of the CO₂ concentration at the airway. To understand the utility of capnography, one must understand dead-space (DS) components and how they affect CO₂ removal from the body.⁵⁹ DS is defined as the portion of the tidal volume (V_T) that does not participate in gas exchange.

$$V_T = DS - V_A$$

The alveolar volume (V_A) is the volume of the inspired gas that reaches well-perfused alveoli. The remainder of the V_T, which equals the DS, can be divided into three subcomponents: apparatus dead space (DS_{ap}), anatomic dead space (DS_{an}), and alveolar dead space (DS_{al}). At the end of inspiration, the respiratory apparatus (e.g., endotracheal tube) is filled with inspired gas that should not contain CO₂. Similarly, all the anatomic airways (trachea, bronchi, and all conducting airways down to the alveoli) should be filled with inspired gas and should therefore contain no CO₂. In this model, there are two types of alveoli: those that are well perfused and those that are not perfused. The alveolar gas should completely equilibrate with the arterial blood and contain CO₂ at the same tension as the arterial blood; ideally, PaCO₂ should equal 40 mm Hg. As the patient expires, the CO₂ detected at the patient's mouth first reflects the DS_{ap} gas having no CO₂; followed by the DS_{an} gas, again with no CO₂; and finally the alveolar gases, containing both DS and well-perfused alveolar gas. When mixed alveolar gas reaches the airway, it produces a rapid rise in the CO₂ concentration to a level somewhere between the concentration in the alveolar gas (40 mm Hg) and the DS_{al} (0 mm Hg), depending on each component's proportion of volume. For example, if half of the alveoli are DS_{al} and PaCO₂ equals 40 mm Hg, then the plateau value of the capnogram should be 20 mm Hg, implying that half of the alveoli are not being perfused. With inspiration, the CO₂ value again drops to 0 until another expiration, and a square wave appears again as the alveolar gas is detected at the mouth. With each breath, there should be a square wave, whose height approaches the PaCO₂ value as the amount of the DS_{al} gas approaches 0.

Algorithm 13-2a. Algorithm for managing a patient on chronic buprenorphine therapy. APS, acute pain service; ICU, intensive care unit; PCA, patient-controlled anesthesia; NSAIDs, nonsteroidal anti-inflammatory drugs.

In a healthy young adult, there is no significant DS_{al} gas, and the end-tidal CO_2 value equals the $PaCO_2$. Therefore, the difference between these values indicates the proportion of DS_{al} in the patient. The presence of a capnogram itself implies that there is metabolism (the production of CO_2), circulation (blood flow to the lungs), and ventilation (respiratory rate and an intact ventilator circuit).

Providing this information on a breath-to-breath basis, the continuous capnogram is extremely useful in many critical situations. It can be used as a surveillance monitor of both the respiratory circuit and the cardiovascular system. Any acute decrease in cardiac output will decrease blood flow to the lungs and increase the DS_{al} , causing an acute drop in end-tidal CO_2 . For this reason, the device was originally used during neurosurgical procedures in the sitting position to detect the presence of air emboli. This principle also allows the detection of pulmonary emboli or any acute drop in cardiac output. In fact, the only acute catastrophic cardiopulmonary problem that will not be detected by the capnometer is arterial desaturation. Therefore, the combination of the capnometer and the pulse oximeter creates a dynamic duo for beat-to-beat and breath-to-breath surveillance of metabolism, circulation, ventilation, and oxygenation.

Circulation Monitors

14 Hemodynamic stability can be monitored by a variety of methods, the most basic of which is systemic arterial blood pressure. Intermittent, noninvasive measurement of systemic blood pressure with an oscillometric blood pressure cuff is the standard in the operating room, and its accuracy equals that of clinical measurements by auscultation. Blood pressure cuffs can be cycled as quickly as once per minute, but when used for an extended duration, they should be cycled no more than once every 3 to 5 minutes. When tighter control or observation is required in patients with significant comorbidities or large swings in hemodynamics due to surgical circumstances, invasive arterial monitoring is used. Although pressure measurements provided by invasive techniques are different from those of noninvasive techniques, they usually coincide closely. A continuous invasive arterial tracing can also be used to assess the adequacy of fluid resuscitation by following the systolic pressure variation (SPV) with positive-pressure ventilation. As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of SPV is inversely related to the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg. A systolic pressure decrease of greater than 10 mm Hg during positive-pressure ventilation implies inadequate preload and the need for more aggressive fluid resuscitation.

In this context, central venous access may be reserved for patients and procedures with the potential for large, rapid volume resuscitation requirements or expected need for potent vasoconstrictors, inotropes, or vasodilators not amenable to peripheral administration. Transesophageal echocardiography (TEE) is now commonly used to assess cardiac function. This technique is easily used in the anesthetized, intubated patient and can quickly assess systolic and diastolic function as well as valvular dysfunction. Increasing familiarity in the use of TEE by noncardiac anesthesiologists may result in the pulmonary artery catheter being reserved for very specific patients demonstrating the need for pulmonary artery pressure monitoring or continuous cardiac output trending.

Finally, a wave of noninvasive continuous cardiac output monitors has gained the attention of surgeons and anesthesiologists alike. These monitors, promising the realization of goal-directed therapy, use indirect means to assess the missing aspect of blood pressure-focused hemodynamic management – stroke volume. Thoracic electrical bioimpedance, pulse wave transit time, peripheral pulse contour analysis, volume clamp, and other methods of estimating stroke volume have been in existence for decades, but have seen a recent rise in interest as variation in intraoperative fluid management may impact surgical outcomes. However, conflicting studies in real-world critically ill patients have failed to establish that these monitors are capable of replacing traditional invasive monitoring routes or are worth establishing as standards of care for all patients undergoing major surgery.⁶⁰ Despite the absence of compelling clinical data, many enhanced recovery protocols have begun including some type of noninvasive cardiac output monitoring to guide fluid therapy.⁶¹ It is unclear whether these monitoring devices offer superior guidance to sound clinical judgment administered by a vigilant anesthesiologist.

“Awareness” and Level of Consciousness Monitors

When delivering a general anesthetic, one of the major imperatives is to achieve and maintain a loss of

consciousness. Normally, this is achieved through careful observation of vital signs (heart rate, blood pressure), physical examination signs (movement in a patient without neuromuscular blockade), and delivery of inhalational or intravenous agents at doses consistent with a loss of consciousness. However, this “science” is inexact and must account for patient age, comorbidities, chronic medications, surgical stimulus, and patient-to-patient variability. As a result, patients may rarely experience “awareness under anesthesia” – a state characterized not only by consciousness but also by recall of intraoperative events. The laypress and public have increased their scrutiny of this perioperative event.

First, appropriate expectations and effective communication of the anesthetic are required. Recent literature has demonstrated that patients undergoing regional anesthesia are as likely to report unpleasant “awareness” as patients undergoing a general anesthetic.⁶² This is despite the reality that loss of consciousness is only a goal of general anesthesia. Clearly, anesthesiologists must communicate the anesthetic plan and expectations more accurately.

Second, several level of consciousness monitors have been developed in hopes of providing the anesthesiologist with additional objective data to guide their assessment and actions. The current generation of monitors generally uses electroencephalographic (EEG) analysis to provide the clinician with an assessment of the relative “depth” of anesthesia achieved. Several commercially available monitors such as the bispectral index (BIS) from Aspect Medical Systems and Entropy from General Electric Healthcare are in common clinical use. Data evaluating the value of these EEG-based monitors in reducing awareness are conflicting, with several large trials producing varying results.^{63,64} As a result, the ASA has not adopted awareness monitors as a standard of care and leaves the decision to use such monitoring technology to each provider, patient, and situation.⁶⁵ The largest, most recent trials have failed to demonstrate a measurable reduction in awareness.^{66,67}

COMMON PROBLEMS IN THE POSTOPERATIVE PERIOD

Postanesthesia care units are required in any setting where surgical procedures are conducted. The increased scope of surgery and the invasive technology used to monitor sicker patients has increased the service at and training required to operate these facilities. In 2014, the ASA revised the Standards for Postanesthesia Care (Table 13-15).

The scoring systems used to assess the postoperative patient direct attention to the primary areas of concern. The postanesthesia recovery score is an attempt to evaluate postanesthesia patient status (Table 13-16).⁶⁸ This basic information should be incorporated in a record that provides clear documentation of postoperative events. Documentation should also include details of postoperative outpatient care, with a note indicating postoperative telephone contact made to elucidate problems. Problems should receive appropriate follow-up, and written postoperative discharge instructions should be provided for the patient.

Investigators have reported that 24% of patients experience a postanesthesia care unit complication. Nausea, vomiting, and the need for airway support constitute 70% of these complications (Fig. 13-2).⁶⁹ The need to maintain airway support was by far the most common respiratory complication. The duration of the procedure as well as ASA classification and type of procedure had a significant bearing on the incidence of complications in this study. Hypothermia was also a common problem that prolonged postoperative postanesthesia care unit stay (Fig. 13-3). Hypothermia has the deleterious effects of altering drug metabolism and delaying recovery. Furthermore, it causes shivering, which increases the metabolic demand for oxygen.

Among cardiovascular complications in the postoperative period, none is more important or more difficult to diagnose than myocardial ischemia. The association of perioperative myocardial ischemia with cardiac morbidity has been clearly documented.²⁶ In a series of high-risk patients undergoing noncardiac surgery, researchers noted that “early postoperative myocardial ischemia is an important correlate of adverse cardiac outcomes.”²⁶ Diagnosis is complicated by the fact that only 10% to 30% of patients suffering documented myocardial infarction have pain and that postoperative ECG T-wave changes are often nonspecific.⁷⁰ Instead, one must seek secondary indications of ongoing ischemia or “angina equivalents,” such as hypotension, arrhythmias, elevated filling pressures, or postoperative oliguria. Arrhythmias are common and are significant primarily because of the association with myocardial ischemia or hypoxemia.

Table 13-15 Standards for Postanesthesia Care

Standards		Criteria to be Fulfilled
Standard I ^a	All patients who have received general, regional, or monitored anesthesia care shall receive appropriate postanesthesia management.	1. A PACU or an area that provides equivalent postanesthesia care shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent <i>except</i> by specific order of the anesthesiologist responsible for the patient's care. 2. The medical aspects of care in the PACU shall be governed by policies and procedures that have been reviewed and approved by the department of anesthesiology. 3. The design, equipment, and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.
Standard II	A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.	
Standard III	On arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.	1. The patient's status on arrival in the PACU shall be documented. 2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse. 3. The member of the anesthesia care team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.
Standard IV	The patient's condition shall be evaluated continually in the PACU.	1. The patient shall be observed and monitored by the methods appropriate to the patient's medical condition. Particular attention shall be given to monitoring oxygenation, ventilation, circulation, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery. This is not intended for application during the recovery of the obstetric patient in whom regional anesthesia was used for labor and vaginal delivery. 2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge, and at the time of discharge. 3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist. 4. There shall be a policy to ensure the availability in the facility of a physician capable of managing complications and providing cardiopulmonary resuscitation for patients in the PACU.
Standard V	A physician is responsible for discharging the patient from the PACU.	1. When discharge criteria are used, they must be approved by the department of anesthesiology and the medical staff. They may vary depending on whether the patient is discharged to a hospital room, to the ICU, to a short stay unit, or home. 2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

ICU, intensive care unit; PACU, postanesthesia care unit.

^aFor nursing care issues, refer to Standards of Postanesthesia Nursing Practice, published by the American Society of Postanesthesia Nurses.

Based on the American Society of Anesthesiologists (ASA)'s Standards for Postanesthesia Care. A copy of the full text can be obtained from ASA, 520 N. Northwest Highway, Park Ridge, IL 60068-2573.

Nausea and vomiting are rarely unifactorial and cause considerable discomfort to patients. Opioids are responsible for stimulating the emesis center in a significant cohort of patients. These patients may provide a clear history of opioid sensitivity and anesthetic and analgesic regimens may be tailored to limit the exposure of these patients to these drugs. In general, however, there is little evidence to favor one anesthetic or anesthetic technique over another, although propofol appears to have an antiemetic effect. Nitrous oxide, often considered causative, does not appear to increase the incidence of nausea according to well-documented studies. It is not unusual for an antiemetic agent to be included preoperatively or as part of the anesthetic technique, especially in patients with a positive history or those deemed to be at risk, such as menstruating young women undergoing laparoscopy. Standard usage includes phenothiazines, butyrophenones, 5HT₃ antagonists, and steroids. A multimodal approach that avoids redosing of a given medication class has been demonstrated to be most beneficial.⁷¹ Despite decades of research, classic medications such as droperidol remain a mainstay of therapy. The FDA recently added a black-box warning to droperidol due to concerns of QT prolongation, but such concerns have not been validated when compared to other perioperative medications; as a result, many institutions continue to use droperidol for postoperative nausea and vomiting prophylaxis.^{72,73}

Table 13-16 Postanesthesia Recovery Score

Parameter	Score
Activity	
Voluntary movement of all limbs to command ^a	2
Voluntary movement of two extremities to command	1
Unable to move	0
Respiration	
Breathes deeply and coughs	2
Dyspnea, hypoventilation	1
Apneic	0
Circulation	
Blood pressure equals 80% of preanesthetic level	2
Blood pressure equals 50–80% of preanesthetic level	1
Blood pressure equals <50% of preanesthetic level	0
Consciousness	
Fully awake	2
Arousable	1
Unresponsive	0
Color	
Pink	2
Pale, blotchy	1
Cyanotic	0

^aPatients should score at least 7 before discharge from the postanesthesia care unit.

Figure 13-2. Major postanesthesia care unit complications by percentage of occurrence and number of patients experiencing each complication. Nausea and vomiting were the most frequently observed complications. ROMI, rule out myocardial infarction. (Reproduced with permission from Hines R, Barash PG, Watrous G, et al. Complications occurring in the postanesthesia care unit: a survey. *Anesth Analg* 1992;74:505.)

Table 13-17 Differential Diagnosis of Delayed Emergence

Metabolic Abnormalities
Hypoxia
Hypercarbia
Hypoglycemia
Hypotension
Hypothermia
Hyponatremia
Drug Effects
Muscle relaxants
Opioids
Barbiturates
Benzodiazepines
Ketamine
Anticholinergics
Inhalational anesthetics
Neurologic Injury
Ischemia
Mass lesions
Seizure disorders

The most common cause of delayed emergence is the residual effects of anesthesia. The differential diagnosis of delayed emergence is best approached by ruling out physiologic, pharmacologic, and neurologic cases, in this order (Table 13-17). There should be little confusion about the implication of muscle relaxants because physical indications of ventilatory distress, combined with the readings of the blockade monitor, should clearly indicate the role of these drugs. Where appropriate, opioids can be reversed using titrated doses of naloxone. Flumazenil can be used for reversal of benzodiazepines.

ENHANCED RECOVERY PROTOCOLS

15 With the increasing adoption of minimally invasive surgical techniques and a realization that postoperative complications may impact intraoperative management, nearly every surgical subspecialty has begun efforts to establish enhanced recovery protocols. These comprehensive care management plans dictate the preoperative preparation, intraoperative management, surgical technique, and postoperative management choices made by all clinicians involved in the patient's care: nurses, anesthesiologists, surgeons, physical therapists, and consultants. While a consistent decrease in length of

stay, complications, and costs has been observed across the many trials assessed in many surgical specialties, there are very few consistent protocols.^{74,75} It appears that the process of collaboration and standardization involved in creating a multidisciplinary and multispecialty protocol may be the most causal attribute in the success of enhanced recovery protocols. While some recommend use of controversial anesthesiology management techniques such as goal-directed colloid fluid therapy, others do not make such recommendations. The evolution of enhanced recovery protocols and implementation science is an active area in all perioperative specialties.

POSTOPERATIVE ACUTE PAIN MANAGEMENT

Postoperative pain is an inevitable consequence of surgery. Its severity is site dependent ([Table 13-18](#)), but the magnitude of the pain experienced by individual patients after similar surgical procedures is influenced by a multitude of factors. Variation in patient experience has been clearly demonstrated by several authors and is reflected in deficiencies in postoperative pain control.⁷⁶ The recognition of this clinical problem has prompted interest in underlying pain mechanisms and in innovative ways to alleviate postoperative suffering.

In 1965, the crucial role of nociceptive C fiber feedback behavior and its modulation by cells in the substantia gelatinosa of the dorsal horn was recognized.⁷⁷ Repetitive stimulation of these fibers by cellular mediators, such as kinins and catecholamines, promotes neural excitation, prolongs repetitive firing, and lowers the threshold to further excitation. As a result, C fibers do not show fatigue, and the stage is set for continuous pain. Counterirritation of large afferent activity has been shown empirically to have beneficial effects. The gate-control theory provides an explanation for the inhibition of C fiber-mediated pain. Serotonergic and enkephalinergic descending inhibitory pathways modulate activity in the dorsal horn before information is relayed to the somatosensory cortex through the spinothalamic tract. The common observation that pain is worse at night, when less sensory information is processed, and that it decreases with daytime activity is an example of how this complex neural system functions.

Superficial somatic pain is well localized and has a protective function. Superficial somatic pain is readily treated by common analgesic techniques. Deep somatic pain may not be well localized; may have some protective function, as in joint immobilization; and is fairly responsive to a variety of analgesics. Visceral pain, served almost entirely by C fiber activity, is poorly localized, often referred, and difficult to treat. In major operations, all modes can be activated, compounding the clinical challenge of providing adequate pain management. These clinical observations direct the focus of postoperative pain management to the treatment of somatic pain by attacking the nociceptor and the subsequent transmission of the painful impulse by the nerve fiber. The use of nonsteroidal anti-inflammatory drugs with or without the injection of local anesthetics into the wound is very effective. If done pre-emptively at the time of surgery, this approach can significantly benefit the patient's postoperative experience. Examples of nerve blocks for various procedures are shown in [Figure 13-4](#).

Table 13-18 Percentage of Patients Who Require Analgesic Injections

Operation	No Analgesic Needed (%)	Three or More Analgesic Injections (%)
Minor chest wall	82	0
Inguinal hernia	52	0
Appendectomy	25	10
Lower abdominal surgery	18	40
Upper abdominal surgery	10	45–65

Figure 13-4. Theoretical relation among dosing interval, analgesic drug concentration, and clinical effects when comparing a patient-controlled analgesia system (*solid line*) to conventional intramuscular therapy (*dashed line*). (Reproduced with permission from White PF. Patient-controlled analgesia: A new approach to the management of postoperative pain. *Semin Anesth* 1985;4:261.)

Table 13-19 Problems That Can Occur During Patient-Controlled Analgesia (PCA) Therapy

Operator Errors
1. Misprogramming PCA device
2. Failure to clamp or unclamp tubing
3. Improperly loading syringe or cartridge
4. Inability to respond to safety alarms
5. Misplacing PCA pump key
Patient Errors
1. Failure to understand PCA therapy
2. Misunderstanding PCA pump device
3. Intentional analgesic abuse
Mechanical Errors
1. Failure to deliver on demand
2. Defective one-way valve at Y-connector
3. Faulty alarm system
4. Device malfunctions

Including potent opioids in the treatment of deep pain, both somatic and visceral, has been routine. However, the responses to standard regimens have been notoriously unreliable, from inadequate pain relief to narcosis, with complications at both ends of the scale. It was not until the 1980s that variations in response were linked to variable serum concentrations of analgesic drugs. Interpatient variation in serum levels to any standard dose can be fivefold, and interpatient therapeutic concentrations can vary on a similar scale. When factored together, there is the potential for a 25-fold variation in patient response to a standard drug prescription. Each patient has an individual therapeutic window. The clinical implications are enormous.

In 1968, investigators demonstrated the virtue of small IV doses given on demand. As a result, the patient experienced greater pain relief, yet used the same or less total narcotic. Although there was significant patient variation, the demand from any individual patient, though cyclic, was constant. Patient-controlled analgesia (PCA) and the technologic and administrative systems to provide it have developed to a point of some sophistication, requiring servicing and a support structure with its own set of problems (Table 13-19). PCA administration requires a receptive environment, education of all personnel, and adequate patient instruction. PCA has received widespread acceptance by patients, nursing staff, and physicians because it provides more prompt and painless analgesia that more closely matches the patient's need over time. PCA is as safe as conventional IM medication. Morphine and meperidine are commonly used drugs, and an example of orders is shown in Table 13-20.

Transdermal narcotic delivery is receiving attention and may become available for postoperative pain. The method is both practical and inexpensive and aims to maintain continuous delivery and constant blood levels. Fentanyl has been the drug of choice and has been well received by patients. The method appears to be safe, but there is a significant lag time between application and the attainment of therapeutic blood levels.

The discovery of endorphins in the 1970s and recognition of their importance in modulating pain at spinal sites led to the supposition that it would be possible to selectively apply opioids directly to

receptors. This led to the development of epidural opiate analgesia, in which opioids are applied directly to the receptors at spinal sites. The goal of epidural analgesia is to obtain maximal analgesia while minimizing systemic side effects. For severe acute postoperative pain caused by major surgery, epidural analgesia has proved to be a superior modality for pain control. In high-risk cases, there is evidence that it has an overall beneficial effect on morbidity.⁴³

Table 13-20 Example of Orders for Patient-Controlled Analgesia (PCA)

1. Patient is to be initiated on PCA with standard monitoring protocol.		
2. Drug selection	Morphine 1 mg/mL	Hydromorphone 0.2 mg/mL
3. Loading initial dose (start PRN for pain)	2–5 mg	0.2–0.5 mg
Maximum total loading dose	10 mg	1 mg
4. Pump setting PCA dose	1–2 mg	0.1–0.2 mg
Lockout interval	6–10 min	6–10 min
4-h limit	30–45 mg	4–5 mg

University of Michigan Hospitals online order form Acute Pain Service, Patient Controlled Analgesia Standard Orders.

Table 13-21 Opioid Protocols in Epidural Opiate Analgesia

	Morphine ^a	Fentanyl ^b
Length of onset	Longer (30–60 min)	Shorter (15–30 min)
Duration	Longer (6–24 h for single bolus)	Shorter (1–2 h for single bolus)
Cephalad spread and side effects	More prone	Less prone
Indication	Favored for lumbar administration after abdominal surgery	Favored for thoracic administration after chest surgery
Dose	Typically 3–5 mg, q6–8h	Typically 50–75 mg/h (±dilute bupivacaine)

^aHydrophilic: slow in, slow out.
^bLipophilic: fast in, fast out.

The effective use of this sophisticated modality requires education and the establishment of protocols with rigorous attention to detail. The potential for respiratory depression demands adherence to monitoring standards. Morphine and fentanyl, often in combination with a dilute local anesthetic solution, are most often prescribed. A typical order form with monitored parameters is shown in [Table 13-21](#).

A comprehensive postoperative pain management service demands resources and must use the physical and pharmacologic modalities available while recognizing the significant subjective component of any individual’s pain problem. The ability to recognize the impact of acute pain or an underlying chronic pain disorder requires that experience be brought to bear on difficult problems. The active involvement of nursing staff and surgeons is essential for the patient to achieve maximal benefit. It is incumbent on the pain-management service to render efficient, continuous, and cost-effective care.

16 Postoperative acute pain management may require a multimodal approach that incorporates opioids, PNB, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization by an anesthesiologist. These patients require very large doses of IV analgesics and need to be maintained orally. The best way to evaluate an appropriate starting dose is to convert the preoperative opioid regimen to an IV morphine equivalent, then add what would be required to treat the acute surgical pain ([Table 13-4](#)). The use of nonopioid and nonpharmacologic treatments is essential in the management of acute postoperative pain in this patient population. PNB, aggressive use of acetaminophen and nonsteroidal anti-inflammatory agents, and novel agents such as dexmedetomidine may be necessary to minimize the adverse effects associated with uncontrolled postoperative pain. As mentioned earlier, these patients may need to be evaluated by an anesthesiologist prior to the day of surgery. This should be an institutional requirement for patients on chronic buprenorphine therapy, as demonstrated in [Algorithm 13-2](#).

Chapter 14

Oncology

Adam C. Yopp and John C. Mansour

Key Points

- 1 Cancer is responsible for nearly 1 in 4 deaths within the United States and is the second leading all-age cause of death, regardless of gender.
 - 2 Five percent to 10% of reported cancers are secondary to familial cancer syndromes.
 - 3 Tobacco use and dietary factors are the two most common environmental risk factors associated with cancer.
 - 4 Population-based screening tests are available for the following cancers: cervical, colon, breast, and prostate.
-

The earliest known description of cancer is documented in a series of Egyptian papyri, the Edwin Smith and George Ebers papyri, written circa 1500 BC. These scrolls detail events approximately 1,000 years earlier, documenting surgical, pharmacologic, mechanical, and magical treatments of cancer. Although illustrated in the papyri, the word “cancer” is first attributed to Hippocrates (460 to 370 BC) nearly a thousand years later. Cancer, the Greek term for crab (“karkinoma”) describes the finger-like spreading projections of an ulcer-forming tumor. Later the Roman physician, Celsus (28 to 50 BC), translated karkinoma into the Latin term cancer, the term most commonly used today. The study of cancer or oncology is attributed to another Greek physician, Galen (130 to 200 AD), who used the Greek word for swelling, oncos, to describe tumors.

EPIDEMIOLOGY

1 Cancer is responsible for nearly 1 in 4 deaths within the United States and is the second leading all-age cause of death, regardless of gender. In 2015, an estimated 1.6 million new cases will be diagnosed and over a half million patients will die of cancer within the United States. In men, the most common forms of cancer are from prostate, lung and bronchus, and colorectal origins. In women, the most common forms are breast, lung and bronchus, and colorectal. Cancers of the lung and bronchus, prostate, and colorectum in men and cancers of the lung and bronchus, breast, and colorectum in women are, in order, the most common cause of cancer-related deaths ([Table 14-1](#)).¹

Although, the overall incidence rate of cancer has been 23% lower among women compared with men since 1992, the rate in men has also declined by –0.6% over the period from 2006 to 2011, largely due to decreases in colorectal, prostate, and lung cancers. During the same time period there was no change in incidence of cancer among women, largely due to the stable rate of breast cancer ([Fig. 14-1](#)).¹

The decline in incidence for the most common cancer types is secondary to improvements in both cancer control and prevention. The long-term decline in colorectal cancer incidence rates since 1985 can be attributed to both changes in associated risk factors and the introduction of effective screening programs. For example, increased rates of diagnostic and therapeutic polypectomies during screening colonoscopies have contributed to declining colorectal cancer incidence rates by interrupting the adenoma to carcinoma sequence.^{2–4} Similarly, lung cancer incidence rates declined in the mid-1980s in men and in the late 1990s in women as a direct result of changed smoking habits.^{1,5,6} In contrast to stable or declining incidence rates in the leading cancer subtypes, increased incidence rates for skin melanoma, esophageal adenocarcinoma, thyroid carcinoma, primary liver carcinoma, kidney carcinoma, pancreas carcinoma, and human papillomavirus (HPV)-related oropharyngeal cancers were observed over the past two decades. Among both men and women the largest increase in annual incidence rates over the last decade was in thyroid cancer and primary liver cancer ([Fig. 14-2](#)).^{1,7}

Throughout most of the 20th century overall mortality rate associated with cancer rose secondary to

smoking-related lung cancer deaths, especially in men, peaking at 215.1 deaths per 100,000 persons in 1991.¹ However, over the past two decades the mortality rate has steadily declined as a direct result of advances in prevention, early detection, and treatment.¹ The most current, 2010 cancer mortality rate estimate is 171.8 deaths per 100,000 persons.¹ Mortality rates for the most common cancers: breast, prostate, and colorectal cancers are down from peak rates by 34%, 45%, and 46%, respectively.^{3,8,9} In contrast, mortality rates are rising for cancers of the oropharynx, anus, liver, pancreas, skin melanoma, and soft tissue. Although thyroid cancer is increasing in incidence the observed mortality rate is stable over time, likely a result of indolent underlying tumor biology and a lead time screening bias (Figs. 14-1, 14-2).¹

RISK FACTORS

Genetic Risk Factors

In 1971, Alfred Knudson described his “two-hit hypothesis” model for retinoblastoma, a rare form of childhood retinal cancer affecting 11.8 patients per one million live births in the United States.^{10,11} In his hypothesis, Knudson postulated that familial retinoblastoma required a first “hit” in the form of an inherited germline mutation and a second “hit” through an acquired mutation for development of retinal tumors.¹⁰ This hypothesis was validated more than two decades later following cloning of *RB1* as the tumor suppressor gene implicated in familial retinoblastoma, thereby ushering in a new frontier of study: cancer susceptibility or familial cancer syndromes.¹²

Table 14-1 Ten Leading Cancer Types for Men and Women by Incidence and Mortality, United States, 2015

Estimated New Cancer Cases			
Males		Females	
Cancer Type	Incidence (%)	Cancer Type	Incidence (%)
Prostate	26	Breast	29
Lung and bronchus	14	Lung and bronchus	13
Colon and rectum	8	Colon and rectum	8

Familial Cancer Syndromes

2 The discovery of inherited mutations of genes associated with an increased risk of cancer provides important opportunities for early detection and prevention of common and rare forms of human malignancies. Genetically related cancer is a spectrum, ranging from common variants with low penetrance to rare variants with either moderate or high penetrance (Fig. 14-3). Linkage studies have successfully identified the majority of familial cancer syndromes through DNA analysis of large families with affected individuals, linking disease phenotypes or cancer subtypes to regions of the genome, with candidate genes subsequently sequenced for a causative mutation. These linkage studies have identified the rare, highly penetrant cancers of hereditary cancer syndromes that account for about 5% to 10% of reported cancers (Table 14-2).¹² The more common, but lower-penetrant variants of genetic, nonsyndrome-related cancers are typically found through large, genome-wide analysis of unrelated persons with common cancers. In genome-wide association studies (GWAS) the entire genome is sequenced and single alterations, or single-nucleotide polymorphisms (SNPs), are used to delineate increased risks of cancer related to genetic risks.¹³

In both high and low penetrant genetically related cancers a high clinical suspicion is necessary for diagnosis and to formulate appropriate screening and treatment plans. To aid the clinician, tools have been developed to obtain an accurate family history, thereby assessing the risk of genetically related cancers (Table 14-3).¹⁴ If the clinician has a reasonable suspicion that a patient may be either at risk for or has a genetically related cancer, further follow-up with a dedicated genetic counselor is recommend.¹⁵ We herein summarize the five most prevalent familial cancer syndromes with regard to genetic mechanism and diagnosis.

Hereditary Nonpolyposis Colon Cancer

Hereditary nonpolyposis colon cancer (HNPCC), previously known as Lynch syndrome, is the most prevalent familial cancer syndrome and is responsible for 2% to 5% of all colorectal cancer.¹⁶ An autosomal dominant syndrome, HNPCC is caused by a germline mutation in one of six genes: *MLH1*, *MSH2*, *MSH3*, *MSH6*, *PMS1*, or *PMS2*.¹⁷⁻²¹ All six of the genes function in DNA mismatch repair and between 45% and 70% of HNPCC families have mutations in the most common gene variants: *MLH1*, *MSH2*, or *MSH6*. Patients with mutations in mismatch repair genes exhibit microsatellite instability, with errors in replication of highly repetitive sequences unable to be repaired, resulting in alterations of the length of the total repeat sequence.

Figure 14-1. Trends in age-adjusted cancer incidence and death by gender, United States, 1975 to 2011. (From Siegel RL, Miller KD, Jemal A. Cancer statistics, 2015. *Ca Cancer J Clin* 2015;65:5-29.)

Figure 14-2. Trends in age-adjusted cancer incidence by gender and site, United States, 1975 to 2011. (From Siegel RL, Miller KD, Jemal A. Cancer statistics, 2015. *Ca Cancer J Clin* 2015;65:5–29.)

Figure 14-3. Genetic architecture by cancer risk.

Clinically, HNPCC is associated with right-sided colonic tumors with histopathology demonstrating poorly differentiated adenocarcinoma and signet ring features. Patients with HNPCC have a 50% to 80% lifetime risk of colorectal cancer, with a median age of diagnosis in the mid-40s. An increased risk of endometrial cancer, ovarian cancer, stomach cancer, small intestine cancer, ureteral cancer, and kidney cancer is also seen in HNPCC kindreds.^{22–24}

Currently, testing for HNPCC is recommended for all newly diagnosed cases of colorectal cancer that fulfill the revised Bethesda guidelines, in families that meet the Amsterdam II criteria, in patients with endometrial cancer diagnosed before age 50, or in families with known HNPCC (Table 14-4).^{25,26}

Table 14-2 Familial Cancer Syndromes

Autosomal Dominant Disorders
Basal cell nevus syndrome (Gorlin syndrome)

Table 14-4 Amsterdam II and Revised Bethesda Guidelines for the Testing of Hereditary Nonpolyposis Colorectal Cancer

Amsterdam II criteria

There should be at least three relatives with a hereditary nonpolyposis colorectal cancer (HNPCC)-associated cancer (cancer of the colorectum, endometrium, small bowel, ureter, or renal pelvis) and the following:

- One should be a first-degree relative to the other two
- At least two successive generations should be affected
- At least one should be diagnosed before age 50
- Familial adenomatous polyposis should be excluded
- Tumors should be verified by pathologic examination

Revised Bethesda guidelines

Tumors from patients should be tested for microsatellite instability (MSI) in the following situations:

- Colorectal cancer diagnosed in a patient who is less than 50 years of age
- Presence of synchronous, metachronous colorectal, or other HNPCC-associated cancers, regardless of age
- Colorectal cancer with MSI histology diagnosed in a patient less than 60 years of age
- Colorectal cancer diagnosed in one or more first-degree relative with an HNPCC-associated cancer, with one of the cancers diagnosed under age 50
- Colorectal cancer diagnosed in two or more first- or second-degree relative with HNPCC-associated cancers, regardless of age

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is a highly penetrant, autosomal dominant syndrome with an incidence between 1 in 5,000 and 1 in 10,000 and is responsible for approximately 1% of all colon cancer cases.²⁷ Arising from a mutation in the antigen-presenting cell (*APC*) gene on chromosome 5q, nearly 75% of cases are due to familial germline mutations with the remainder secondary to first-generation de novo mutations.²⁸

Clinically, FAP manifests with hundreds to thousands of adenomatous polyps at a young age with a resultant risk of colon cancer of 90% by age 45.²⁹ In addition to colonic manifestations, duodenal and gastric polyps are also prevalent with a lifetime risk of duodenal cancer ranging from 5% to 12%, typically periampullary in location. Benign, extraintestinal manifestation of FAP includes desmoid tumors, mesenteric fibrosis, epidermoid cysts, osteomas, congenital retinal pigment epithelium, and dental anomalies and typically accompanying adenomatous polyp formation.²⁹

Hereditary Breast and Ovarian Syndrome

Hereditary breast and ovarian syndrome (HBOC) occurs at an incidence rate of 1 in 500 or 1,000 and is inherited in an autosomal dominant fashion with a penetrance of nearly 85%.^{30,31} Germline mutations in *BRCA1* (chromosome 17q) or *BRCA2* (chromosome 13q) are responsible for approximately 60% of HBOC, with mutations in *ATM*, *NBM*, *BRIP1*, *CHEK2*, *TP53*, *PTEN*, and *RAD51C* responsible for the remaining cases.^{32,33} *BRCA1* and *BRCA2* are DNA damage repair genes and more than 1,000 variants have been identified with founder *BRCA* mutations documented in genetically isolated populations.³⁴ In the United States, the most common founder mutations occur in Ashkenazi Jewish lineage with nearly 1 in 40 carrying the common *BRCA1* or *BRCA2* mutations.³⁴ Genetic linkage studies of families with HBOC syndrome demonstrate that the lifetime risk of developing breast and ovarian cancers by age 70 is 56% and 17%, respectively.^{30,32}

Familial Gastric Cancer

Hereditary diffuse gastric cancer (HDGC) is autosomal dominant in nature and is characterized by diffuse gastric cancer and lobular breast cancer with a nearly uniform penetrance and an 80% lifetime risk of gastric cancer.³⁵ The average age of developing hereditary gastric cancer is 38 years. Thirty to 40% of families with HDGC have germline mutations in *CDH1* at chromosome 16q, a gene producing the E-cadherin protein necessary for cell proliferation and adhesion within the stomach mucosa.³⁶ Currently, the diagnosis of HDGC is suspected if a person or family meets any of the below criteria³⁷:

- At least two cases of stomach cancer in a family, with at least one being diffuse gastric cancer diagnosed before age 50
- At least three cases of stomach cancer at any age
- Diagnosis of diffuse gastric cancer before the age of 45
- Diagnosis with both diffuse gastric cancer and lobular breast cancer

von Hippel–Lindau Disease

von Hippel–Lindau Disease (VHL) is an autosomal dominant syndrome characterized by the formation of hemangioblastomas of the brain, spinal cord, and retina.³⁸ In addition, individuals with VHL disease may develop renal or pancreatic cysts and are at an increased risk for clear cell renal cell carcinoma, pheochromocytomas, and pancreatic neuroendocrine tumors. Arising from a germline mutation of the

VHL gene on chromosome 3p, the protein product degrading hydroxylated hypoxia inducible factor-1 α , nearly 80% of cases are familial.³⁹ Unlike most autosomal dominant disorders, *VHL* disease subscribes to the Knudson “two-hit hypothesis” with mutation of both *VHL* alleles necessary for tumor or cyst formation.³⁸

Environmental Risk Factors

Although the cause of most human cancers remains unidentified, the causal association between carcinogenesis and exposure to environmental risk factors is significant. The first known documented link between cancer and exposure to a carcinogen was documented in the treatises of the English surgeon Percivall Pott.⁴⁰ In 1775, Pott documented the high incidence of scrotal cancer among chimney sweeps secondary to soot lodging in scrotal skin. Subsequent preventive measures aimed at increasing bathing and use of protective clothing led to a dramatic decline in the incidence of scrotal cancer. It was not until the 20th century that the active carcinogens in soot were shown to be polycyclic aromatic hydrocarbons.⁴¹ [Table 14-5](#) lists the most common carcinogens associated with human cancers.

Table 14-5 Preventable Exposures Associated with Human Solid Organ Cancers

Cancer Site	Carcinogenic Agents with Sufficient Evidence
Oral pharynx and tonsil	Alcoholic beverages, betel quid, HPV type 16, tobacco (smoking and smokeless)
Nasopharynx	Epstein–Barr virus, formaldehyde, tobacco (smoking)
Esophagus	Alcoholic beverages, betel quid, tobacco (smoking and smokeless), gamma radiation
Stomach	<i>H. pylori</i> , tobacco (smoking), gamma radiation
Colon and rectum	Alcoholic beverages, tobacco (smoking), gamma radiation
Anus	HIV type 1, HPV type 16
Liver and bile duct	Aflatoxins, alcoholic beverages, <i>Clonorchis sinensis</i> , HBV, HCV, <i>Opisthorchis viverrini</i> , plutonium, thorium-232, tobacco (smoking), vinyl chloride
Pancreas	Tobacco (smoking and smokeless)
Lung	Arsenic, asbestos, beryllium, cadmium, chromium, coal, nickel, outdoor air pollution, painting, plutonium, radon-222, silica, soot, sulfur, tobacco (smoking and second hand), gamma radiation
Skin (melanoma)	Solar radiation, ultraviolet-emitting tanning, polychlorinated biphenyls
Pleura (mesothelium)	Asbestos, painting
Breast	Alcoholic beverages, diethylstilbestrol, estrogen–progestogen contraceptives and menopausal therapies, gamma radiation
Cervical	Diethylstilbestrol, estrogen–progestogen contraceptives, HIV, HPV types 16,18,31,33,35,39,45,51,52,56,58,59, tobacco (smoking)
Ovary	Asbestos, estrogen menopausal therapy, tobacco (smoking)
Kidney	Tobacco (smoking), gamma radiation, trichloroethylene
Thyroid	Radioiodines, gamma radiation

Tobacco and Cancer

Tobacco use is associated with more cancer-related deaths worldwide than any other environmental risk factor. There are now 19 cancers for which causal evidence exists between cancer formation and cigarette smoking: lung, oral cavity, nasopharynx, nasal cavity, larynx, esophagus, liver, stomach, colorectum, pancreas, kidney, ureter, urinary bladder, cervix, ovary, and bone marrow. Three cancers have known causality with smokeless tobacco use: oral cavity, esophagus, and pancreas.⁴² [Table 14-6](#) details the relative risks by cancer site of tobacco smoking.

The causative carcinogens in tobacco products are broad and heterogeneous. In fact, the International Agency for Research on Cancer (IARC) working group has identified 72 carcinogens contained in cigarette smoke linked to cancer development.⁴³ The underlying pathophysiology for smoking-related cancer is organ specific but likely dependent on the oxidative damage caused by the carcinogens producing free oxygen radicals and redox cycling.⁴⁴

Viral Risk Factors

Nearly 15% of cancers or 1.3 million cancer cases worldwide can be attributed to viral infection.⁴⁵ The search for human tumor viruses is accentuated by a long appreciation of viral-linked cancers in birds

and rodents. Peyton Rous in 1911 demonstrated spindle cell sarcomas could be readily transmitted from diseased to healthy chickens using tumor cell infiltrates.⁴⁶ This observation led to the identification of the Rous sarcoma virus (RSV), a member of the *Retroviridae* family, as causative agent responsible for Rous’ original observation decades earlier.⁴⁶

The lack of convincing animal models confirming epidemiologic studies coupled with the lack of oncogene expression by human tumor-associated viruses has delayed recognition of virus-induced human cancers. Using both epidemiology and molecular biology analysis, six viruses are established as causative agents of cancer (Table 14-7). Hepatitis B and C viruses (HBV and HCV), HPV, and the human herpes virus 8 (HHV-8) (Kaposi sarcoma-associated herpes virus) will be discussed in further detail.

Table 14-6 Cancer Sites Associated with Tobacco Smoking by Relative Risk According to the International Agency for Research on Cancer Working Groups

Cancer Site	Average Relative Risk
Lung	15–30
Larynx	10
Oro- and hypopharynx	4–5
Urinary tract	3
Esophagus (squamous)	2–5
Pancreas	2–4
Esophagus (adenocarcinoma)	1.5–2.5
Stomach	1.5–2.5
Liver	1.5–2.5
Uterine cervix	1.5–2.5

Adapted from Sasco AJ, Secretan MB, Straif K. Tobacco smoking and cancer: a brief review of recent epidemiological evidence. *Lung Cancer* 2004;S3–S9.

Table 14-7 Human Tumor–Associated Viruses

Virus	Family	Cancer Type	Oncogene
Hepatitis B	Hepadnaviridae	Hepatocellular carcinoma	X protein
Hepatitis C	Flaviviridae	Hepatocellular carcinoma	None
Epstein–Barr	Herpesviridae	Burkitt lymphoma, Hodgkin lymphoma, nasopharyngeal carcinoma	LMP-1
Human papillomavirus	Papillomaviridae	Cervical, anal, penile, and head and neck cancers	E6/E7
Human T -lymphotropic virus type 1	Retroviridae	Adult T-cell leukemia	Tax
Kaposi sarcoma	Herpesviridae	Kaposi sarcoma, pleural effusion lymphoma, multicentric, Castleman disease	vGPCR,vIL-6, vBcl2, vMIPs, vFlip, vCyclin, LANA

Hepatitis B and Hepatitis C Viruses

HBV and HCV are hepatotropic viruses causing both acute and chronic viral hepatitis and are responsible for nearly 90% of hepatocellular carcinoma (HCC) cases diagnosed worldwide.⁴⁷ HBV, a member of the *Hepadnaviridae* family, is a circular double-stranded DNA that incorporates into the cellular DNA of hepatocytes at random sites. Although the exact mechanism for induction of HBV-related HCC remains unknown due to the long latency period between viral infection and cancer appearance it is postulated to occur through either (1) induction of chronic liver cell injury leading to random chromosomal and genetic injury or (2) expression of X protein from the incorporated HBV activating the mitogen-activated protein kinase, c-jun N-terminal kinase, protein kinase C, phosphatidylinositol 3-kinase, protein kinase B, and JAK/STAT pathways.^{48–51}

HCV is a single-stranded RNA virus from the *Flaviviridae* family, unique as the only human tumor virus utilizing RNA as genetic material. Responsible for the vast majority of HCC cases within the United States, HCV has six known genotypes and has a latency period from infection to HCC formation typically more than two decades. The actual pathophysiologic mechanism for HCV-related HCC development is unknown but like HBV-related HCC is thought to occur secondary to creating a state of chronic inflammation and regeneration within the liver parenchyma at the hepatocyte level.^{52,53}

With the development of a HBV vaccine in the late 1970s the incidence of HBV-related HCC has decreased worldwide. Although there is no commercially available HCV vaccines, since 2010 there are orally bioavailable drugs that dramatically decrease the HCV viral load. However, it is unclear whether

HCV treatment will impact HCC incidence rates as many patients have already progressed to cirrhosis prior to actual HCV diagnosis.

Human Papilloma Virus

HPV is a nonenveloped double-stranded DNA tumor virus that is responsible for a variety of epithelial disorders ranging from benign to malignant. Although consisting of over 100 known variants, HPV-16 and HPV-18 are designated high risk for tumor induction and are responsible for over 70% of known cervical and anal cancers.^{54,55} The molecular pathogenesis of HPV-related cancers is better understood than other viral-associated cancers and occurs following HPV infection of keratinocytes at the basal epithelial layer of the stratified squamous epithelium. Upon HPV integration into host DNA, two viral genes, E6 and E7, are expressed and their products bind to a *p53* tumor suppressor gene (E6) and/or retinoblastoma suppressor protein (E7) to deregulate cell growth and inhibit apoptosis leading to the accumulation of mutations and the development of cancers following a length latency period.^{56,57} The recent development of quadrivalent and bivalent HPV vaccines is expected to have a significant impact on the development of HPV and subsequent cervical and anal cancer incidence.⁵⁸

Human Herpes Virus 8

HHV-8, also known as Kaposi sarcoma-associated herpes virus, is a double-stranded DNA virus from the *Herpesviridae* family associated with the development of Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease. HHV-8 has a latent and lytic phase persisting in B-lymphocytes. During the latent phase HHV-8 evades the host immune system and has only minimal expression of gene products. However, in the lytic phase innumerable viral proteins are produced including viral G protein-coupled receptor, K1, v-cyclin, and v-Bcl-2 that modulates cell growth, induces vascular endothelial growth factor (VEGF) expression, and inhibits apoptosis, respectively, leading to induction of cancer.^{59,60}

Dietary Risk Factors and Obesity

3 Dietary factors are thought to account for nearly 30% of cancer cases in developed countries, making dietary factors second only to tobacco use as the most preventable cause of cancer.⁶¹ The contribution of diet to cancer risk in developing countries is considerably lower, most estimates indicate a 20% causal rate.⁶² Attaining definitive evidence to confirm or refute effects of specific dietary factors on cancer incidence is oftentimes difficult with causal associations relying on migration patterns of immigrants. Migration studies have demonstrated that the incidence of many cancers change as much as 5- to 10-fold among immigrants over time, approaching that of the host country. The age at migration appears linked to cancer development among first-generation immigrants, suggesting that the susceptibility to environmental carcinogenic influences varies with age by cancer type.⁶³⁻⁶⁵ Table 14-10 lists cancer sites with causal associations with dietary factors.

Obesity

The most important impact of diet on the risk of cancer is mediated through body weight. The IARC working group on weight control and physical activity estimates in developed countries a body mass index over 25 kg/m² accounts for approximately 39% of endometrial, 25% of kidney, 11% of colon, 9% of postmenopausal breast cancer, and 5% of total cancer incidence.⁶⁶

The mechanisms linking obesity and cancer development are largely unknown but likely multifactorial. An example of a causal association between cancer and obesity is in postmenopausal breast cancer. A weight gain of 10 kg or more is associated with a significant increase in breast cancer incidence among women who have never used hormone replacement therapy.⁶⁷ This is likely secondary to large increases in endogenous estrogen levels, also leading to increased incidence of endometrial cancer.⁶⁸ The mechanism for obesity-related nonbreast or nonendometrial cancers remains unclear and is under clinical investigation.

Table 14-8 Human Cancers Associated with Dietary Factors and Nutrition

Dietary Factor Associated with Increased Cancer Risk	Cancer Site
Overweight and obesity	Esophagus, colorectum, breast, endometrium, kidney
Alcoholic beverages	Oral cavity, pharynx, larynx, esophagus, liver, breast
Aflatoxin	Liver
Chinese-style salted fish	Nasopharynx

Cell Cycle

Control of the cell division cycle is central for governing when the cell should progress to DNA synthesis and proliferation versus growth arrest, DNA repair, or apoptosis. Cell division proceeds through a well-defined series of stages with tightly regulated and balanced processes dependent on oncogene and tumor suppressor gene expression (Fig. 14-4). When cells leave quiescence (G_0), they enter a first gap phase (G_1) where an explosion of growth factors and macromolecules is transcribed and translated allowing cells to divide but not lose overall size. Toward the end of G_1 , cells reach a restriction point governed by cell cycle checkpoint genes where thereafter they are now committed to division. It is at this restriction point where DNA repair or programmed cell death (apoptosis) occurs and where phosphorylation of the tumor suppressor product, RB protein, allows entry into the S phase. During the S phase, DNA is synthesized and progression to second gap phase (G_2) follows. Within the middle of the G_2 phase yet another restriction point or cell cycle checkpoint occurs prior to cell entry into mitosis (M), the actual cell division phase.⁶⁹

Proto-oncogenes code for proteins that send signals to the cell nucleus promoting cell division, especially at the G_1 -S and G_2 -M transition points. Oncogenes are altered versions of proto-oncogenes also coding for signaling proteins but in a continuous fashion leading to incontrollable cell division and thus, tumor development. The conversion of proto-oncogenes into oncogenes occurs through three basic methods: (1) a mutation within a proto-oncogene producing an increase in protein activity (seen in the conversion of the *Ras* proto-oncogene), (2) an increase in the amount of protein within the cell resulting in amplified expression (i.e., *c-MYC* proto-oncogene), and (3) a chromosomal translocation where fusion proteins are produced or protein expression is altered (i.e., Philadelphia chromosome, *BCR/ABL*).⁷⁰

Tumor suppressor genes also play a crucial role in the cell division cycle serving as a brake for division in response to DNA damage. The tumor suppressor genes, *p53* and *RB*, play a critical role in maintaining the checkpoint at the G_1 -S transition point.^{71,72} Homozygous loss of *p53* is found in 65% of colon cancers, 30% to 50% of breast cancers, and 50% of lung cancers. In addition, *p53* germline mutations are associated with Li-Fraumeni syndrome, an autosomal dominant disorder associated with sarcomas, breast cancer, leukemia, and adrenal gland cancers.⁷³

Cancer Immunology

The fundamental tenet of the immune surveillance hypothesis, postulated by Thomas and Burnet nearly five decades ago, is that the underlying function of the immune system is to survey the human body, recognize and then eliminate tumors based on tumor antigen expression.^{74,75} Well documented in nonhuman animal models, the role of the immune system as a surveillance and treatment response in human malignancies is debatable and is best supported by tangential clinical evidence. In humans, cancer incidence rates correlate to advancing age presumably due to increased cell division and error rates in chromosomal replication over time that the immune system simply cannot overcome.

A corollary to the immune surveillance hypothesis is that immunodeficient individuals have an increased rate of cancer development.⁷⁶ Epidemiologic studies of patients with heritable immunodeficiencies demonstrate mixed results for this hypothesis. Incidence rates of traditional noncommon cancers including Kaposi sarcoma and lymphoblastic lymphoma have demonstrated increased frequency in heritable immunodeficiencies.⁷⁷ However, common epithelial-based cancers, including lung, colorectal, and breast, have similar incidence rates as the general population.⁷⁷ The initial epidemiologic studies were conducted at a time when patients with heritable immunodeficient disorders rarely lived past 30 years of age, so it is difficult to ascertain whether subtle changes in incidence seen in the more common epithelial cancers are more obvious as patients age. A similar phenomenon is seen in acquired immunodeficiencies, including acquired immunodeficient syndrome (AIDS), where uncommon cancers such as Kaposi sarcoma and non-Hodgkin lymphoma and not epithelial-based tumors remain the most common AIDS-related cancers.⁷⁸ As HIV-positive individuals are living longer due to more efficacious antiretroviral treatments, common epithelial cancers as well as

cancers secondary to viral coinfectivity, with hepatitis viruses and/or HPV have increased in incidence.^{79,80}

Figure 14-4. Mammalian cell cycle. Rb, a tumor suppressor gene, is complexed to E2F and is thereby unable to enter from G₁ to S phases. Upon signaling from the checkpoint genes, CDK4, 6, and cyclin D, Rb is phosphorylated allowing passage into S phase.

Another cohort, with an acquired immunodeficiency, demonstrating increased incidence rates of common and noncommon cancers are patients receiving immunosuppressive drugs following transplantation. A recent study examining cancer incidence in patients following heart and/or lung transplantation receiving immunosuppression therapy demonstrated a sevenfold increased incidence of cancer compared to the general population, with leukemia and lymphoma being the most prevalent.⁸¹ Additionally, nearly a 200-fold increase in basal and squamous cell carcinomas is demonstrated following renal transplantation, secondary to immunosuppression and UV radiation damage.⁸²

Tumors differ fundamentally from their normal cell counterparts through the production of tumor antigens, thereby allowing the immune system to differentiate self versus nonself. Tumor antigens are generated by the tumor cell and have historically been broken into two groups, tumor-specific antigens and tumor-associated antigens.⁷⁶ Tumor-specific antigens are molecules, typically proteins produced by the tumor secondary to a mutation of a proto-oncogene or tumor suppressor gene. Tumor-associated antigens are proteins produced following gene mutations unrelated to tumor formation. Due to lack of specificity between the two historical terms, tumor antigens are more accurately classified according to mutation of normal self-proteins, overexpression or aberrant expression of normal self-proteins, glycoproteins, or glycolipids, and formation of protein products of oncogenes or oncoviruses.⁷⁶

The innate immune system response to tumors can be divided into two general compartments: a set of barriers and cell activity.⁸³ The barriers are comprised of mechanical factors including the skin and mucous membrane, chemical factors including high gastric acidity, and biologic barriers including commensal microbes. Natural killer cells, macrophages, and dendritic cells comprise the cellular component of the innate immune system response.

Natural killer cells constitute the primary innate immune cell type responsible for killing nonmajor histocompatibility complex (MHC) expressing cancer cells. Many tumors lose MHC class I molecules during malignant transformation while continuing to express ligands such as MICA and MICB that constitutively bind NK receptors, including NKG2D, inducing tumor cell apoptosis through perforin and granzyme release.⁸⁴ Macrophages can efficiently eliminate apoptotic tumor cells through the release of lysosomal enzymes, reactive oxygen intermediaries, and nitric oxide. Dendritic cells link the innate immune system to the adaptive immune system. Residing in specific tissues according to dendritic cell lineage, dendritic cells phagocytize tumor antigens and carry the proteins to draining lymph tissue presenting to tumor-specific T cells. Depending on the state of dendritic cell maturity caused by costimulatory molecule signaling, either a state of anergy/tolerization (immature) or activation (mature) of tumor-specific T cells and the adaptive immune system response occur.⁷⁶

Evidence supporting activation of the adaptive immune system response in mouse tumor cell models is well documented. However, its role in human malignancies is not as clearly defined due to the heterogeneity of the tumor microenvironment and the obvious lack of immunodeficient human models. Nevertheless, compelling clinical data supports the hypothesis that an adaptive immune system response serves as a mechanism for tumor cell death in humans. Tumor infiltrating lymphocytes (TILs) including

CD8⁺ T cells, natural killer cells, or natural killer T cells have been associated with improved prognosis for a number of different tumor types.^{85–88} The initial association between favorable prognosis and TILs was first observed in melanoma patients where it was reported that patients with higher levels of CD8⁺ T cell tumor infiltration survived longer than patients with tumors containing lower numbers.⁸⁵ The mechanism of TILs and especially CD8⁺ T-cell-mediated tumor elimination requires tumor antigen presentation by APCs, typically dendritic cells. Activation of CD8⁺ T cells occurs following binding of MHC class I molecules expressed by APCs and costimulatory molecule expression. The most widely studied costimulatory molecule pathway is the B7-CD28 interaction with B7 expressed on APCs and CD28 on CD8⁺ T cells. Following CD8⁺ T-cell activation, intracellular signaling activation of the NF-AT, NF- κ B, and AP1 pathways leads to further CD8⁺ T-cell activation and promotion of tumor cell death.⁷⁶

Although the original immune surveillance hypothesis is critical to understanding cancer cell eradication it is likely that tumor cell tolerance and evasion play a much more important role in tumor cell growth, thus offering opportunities for development of novel immunotherapies. The most successful molecules to be targeted in clinical cancer immunotherapy are the immune checkpoint receptors, cytotoxic T-lymphocyte-associated antigen 4 (CTLA4), and programmed cell death protein 1 (PD1). Both PD1 and CTLA4 are inhibitory receptors that regulate immune responses at different levels and via different mechanisms (Fig. 14-5).⁸⁹

CTLA4, the first immune checkpoint receptor to be clinically targeted, is expressed exclusively on T cells, where it primarily regulates the amplitude of the early stages of T-cell activation. Although expressed on activated CD8⁺ T cells, the major physiologic role of CTLA4 appears to be through effects on CD4⁺ regulatory (T_{reg}) and helper cells. Thus, blockade of CTLA4 appears to switch the tumor microenvironment from immunosuppressive to immunoreactive.^{90,91} An antihuman CTLA4 antibody, ipilimumab, was shown in a cohort of patients with advanced melanoma to induce an objective response rate in tumors previously treated with IL-2. Although there is significant immune-related toxicity involving skin, liver, or colon, ipilimumab has gained FDA approval for the treatment of advanced melanoma.⁹²

In contrast to CTLA4, the major role of PD1 is to limit the activity of T cells in peripheral tissues at the time of T-cell activation to tumor antigen presentation. Similar to CTLA4, PD1 is highly expressed on T_{reg} cells acting as a suppressor mechanism to effector T cells (CD8⁺ T cells).⁹³ Currently, two anti-PD1 inhibitors, pembrolizumab and nivolumab, have demonstrated efficacy in advanced melanoma patients with disease progression following ipilimumab treatment.^{94,95}

The Role of the Surgeon in Cancer Management

For many patients, surgeons are the entry point into the healthcare system when managing cancer and cancer-related illness. For many surgeons, palliative or supportive care for patients with incurable malignancy comprises a significant portion of their practice. Surgeons are involved in every phase of cancer care from diagnosis to palliation. Many of the concepts covered in this chapter are covered on a disease-specific basis elsewhere in the textbook. Understanding the concepts underpinning many of the treatment approaches can help surgeons understand the rationale for current practice, and can also potentiate the development of new therapeutic strategies.

Figure 14-5. A: Upon antigen expression to the T cell receptor on memory or naïve T cells and subsequent stimulation, CTLA4 is transported to the T cell surface dampening further T cell activation. **B:** The activity of PD1 is further downstream in the inflammation process. PD1 is induced by activated T cells within peripheral tissues and signals to dampen further effector T-cell activation-limiting inflammatory cascade. (Adapted from Pardoll DM. The blockade of immune checkpoints in cancer immunotherapy. *Nat Rev Cancer* 2012;22:252–264.)

Surgical Intent

Although a significant portion of oncologic surgery practice focuses on curative resection of disease, the intent for many surgical situations does not include cure. Recognizing the goals of therapy prior to initiating a treatment course can help surgeons maintain a patient-centered approach with appropriate patient preoperative counseling and consent.

Diagnosis and Staging

The role of surgical biopsy to confirm the diagnosis of cancer prior to definitive therapy has been diminished recently by the advances of image-guided and endoscopic biopsy techniques. These techniques allow high levels of diagnostic accuracy with reduced patient discomfort, expense, and use of hospital resources. Procedures such as punch biopsy for suspicious cutaneous lesions or excisional lymph node biopsy for characterization of lymphoma still remain a common diagnostic procedure for many surgeons.

A key aspect of these biopsies is a clear communication with the responsible pathologist regarding specialized tissue handling or preservation prior to initiation of the procedure. Specimen marking and orientation are critical for subsequent resection needs. Incorrect preservation of the biopsy specimen may obviate the possibility for flow cytometry when attempting to characterize lymph node suspicious for lymphoma. Intraoperatively, surgeons need to plan for a subsequent definitive resection when appropriate. Forethought in the selection of an incision or the extent of tissue plane dissection and disruption can make a subsequent definitive resection less morbid and less complex for the patient and surgeon. For instance, on occasion, extremity soft tissue tumors may require excisional biopsy. A longitudinal incision in the orientation of the affected limb can minimize the size of the incision during the subsequent definitive resection.

Surgeons may also play a key role in the staging of cancers. As entry points into the healthcare system for patients dealing with cancer, surgeons are often responsible for distilling the physical examination, radiologic, endoscopic, and surgical findings into a clinical stage assignment. For cancers, such as pancreatic adenocarcinoma, gastric adenocarcinoma, and ovarian cancer, the operative assessment of the peritoneum may identify radiographical occult carcinomatosis 10% to 25% of the time.^{96–99} When performed laparoscopically in well-selected patients, this minor procedure can avoid the patient impact of a nontherapeutic laparotomy in the setting of metastatic, incurable cancer. In addition, lymphadenectomy, which will be discussed more fully elsewhere, serves an important prognostic role by allowing for complete staging of the nodal basins. The status of the nodal basins not only has important prognostic impact, but also defines the role of adjuvant therapy for many different cancer types.

Curative Resection

The ability to completely resect all viable tumors requires consideration of technical, oncologic, and functional resectability. A small number of tumor types are associated with surgical survival benefit in the setting of incomplete resection. Patients with cancers such as ovarian cancer and mucinous appendiceal cancer may benefit from cytoreduction with the possible addition of intraperitoneal chemotherapy.^{100–104} Patients with life-limiting hormonal symptoms related to metastatic neuroendocrine tumors may gain survival benefit from cytoreduction and the resulting decrease in circulating hormones, such as insulin and somatostatin.^{105,106} However, for the vast majority of cancers, survival benefit of resection is only associated with complete resection.^{107–110} For that reason, a plan for resection should include extirpation of all viable tumor for patients with a treatment goal of cure.

The goals for curative resection should include not only complete removal of tumor, but also preservation of adequate patient function and the possibility of prolonged disease-free survival (DFS). These functional and oncologic aspects of resectability are the metrics by which any planned resection can be judged successful. For instance, the role of resection of hepatic colorectal metastases or hepatocellular cancer is defined to a great degree by the amount of healthy residual liver and not necessarily the volume of liver tumors.^{111–113} Conversely, even small-volume hepatic metastasis in the

setting of pancreas adenocarcinoma precludes resection for curative intent.¹¹⁴ Resectability for patients with colorectal hepatic metastases relies on functional preservation; resection for patients with pancreas cancer metastases is limited by oncologic outcomes.

Palliative Surgery

Symptoms related to the progression of malignant disease are a common problem faced by surgeons. A significant proportion of a surgeon’s oncologic practice can be dedicated to providing palliation for patients with incurable conditions. This need is not limited to patients with malignancy; however, the principles associated with surgical palliation of cancer-related symptoms are a sound model for discussion regarding surgical palliation in general.

The primary concept driving decision-making for patients with palliative needs is the critical starting point of goal assessment. In order to deliver the most individualized, risk-appropriate, effective palliation to any given patient, surgeons need to ascertain the goals of therapy for each individual patient at that given time. This assessment transcends diagnosis-based treatment algorithms or pathways. Patients with gastric outlet obstruction related to metastatic gastric cancer may seem like a homogeneous group; however, the primary therapeutic goals of individual patients may vary dramatically. Treatment goals in that setting may include resolution of nausea, eating independently, long-term maintenance of nutrition, or improving performance status sufficiently to enter home hospice. These variable treatment goals can lead to variable treatment strategies, such as placement of a nasogastric decompression tube, a percutaneous gastrostomy tube, gastrojejunostomy, and/or antiemetic medications.

A second factor particularly relevant to palliative surgery for patients with cancer is the increased risk for many procedures in a population with incurable malignancy. Many patients eligible for palliative operations or procedures have been debilitated by malnutrition, physical deconditioning, prolonged hospitalization, or cytotoxic chemotherapy.^{115,116} These factors, as well as the presence of metastatic disease, have all been associated with poor short-term outcomes following operations. Understanding the increased risks of even simple operations for this patient population can help the surgeon guide the patient and family conversations regarding the risks and benefits of a procedure. Making a decision with a patient and family regarding strategies for surgical palliation requires both an individualized assessment of the needs of those involved as well as a generalized awareness of the risks for that procedure based on associated risk factors.

Extent of Resection

For malignancies such as melanoma, breast cancer, or sarcoma, the requirement for radical resection has decreased significantly over the past several decades.^{117–121} Conversely, for diseases such as pancreas cancer and liver tumors, the frequency and safety of radical resections have increased dramatically over that same time period.¹²² A key point of judgment for surgeons involved in cancer operations is not only deciding when to operate, but also how extensive that operation should be.

Pathologic Margins

An important distinction must be made between surgical and pathologic margins. Surgical margins are the planned lines or planes of resection around a grossly visible tumor. The aim of this strategy is not to ensure a wide swath of healthy tissue around the tumor specimen, but to ensure a final negative pathologic margin. Pathologic margins are the histologically assessed borders of uninvolved tissue around the microscopic tumor. Tumors with infiltrative behavior may extend up to the pathologically assessed margin even though the grossly assessed surgical margin appears to be uninvolved. An example of this discrepancy occurs in the management of melanoma. Resection with a 1-cm surgical margin is generally considered adequate for a nonmetastatic extremity lesion with a tumor thickness of 1 to 2 mm. If the final pathologic margin is only 0.3 mm, this is considered a negative, and adequate, pathologic margin.

Table 14-9 Terms Typically Used to Describe Pathologic Margins for Cancer Resections

Margin Category	Microscopically Negative Pathologic Margin	Grossly Negative Surgical Margin
R0	x	x
R1		x
R2		x

The terms typically used to describe pathologic margins for cancer resections are defined below (Table 14-9). An R0 margin is typically considered negative and an R2 margin is considered grossly positive. For many, but not all, types of cancer, the presence of an R1 margin is associated with increased risk of recurrence. Management of a positive pathologic margin is dependent on technical and oncologic factors associated with that particular tumor. For instance, some early-stage cutaneous malignancies such as dermatofibrosarcoma protuberans or basal cell cancer are characterized by limited risk of distant disease dissemination and a high risk of local recurrence in the setting of positive pathologic resection margins. In a location where additional local excision may not be limited by adjacent structures, an effort for reexcision of a positive margin may be reasonable. Alternatively, the presence of cancer at the superior mesenteric artery (SMA) resection margin at the time of pancreaticoduodenectomy does not lead to an additional operative attempt to achieve a negative final margin for patients with pancreas adenocarcinoma. The hesitation to attempt reresection is driven not only by the technical challenges of attempting to achieve a broader margin along the SMA, but also by the very high risk of distant recurrence for those patients and the relatively lower impact of local recurrence in this setting.¹²³⁻¹²⁵

Lymphadenectomy

The removal of regional lymph nodes at the time of resection of the primary tumor has been the focus of significant investigation and controversy throughout the contemporary history of surgical management of cancer. The surgical principles attributed to William Halsted regarding the surgeon's role in interrupting the progression of cancer from the primary tumor through lymphatic channels to regional lymph nodes and then to distant sites form the traditional rationale for regional lymphadenectomy.^{126,127} However, more contemporary studies such as MSLT-1, the Dutch Gastric Cancer Lymphadenectomy, and ACOSOG Z0011 clinical studies have raised questions regarding the survival benefit of lymphadenectomy for patients with melanoma, gastric cancer, and breast cancer, respectively.¹²⁸⁻¹³¹

The potential prognostic benefits of lymphadenectomy undoubtedly are more germane than therapeutic advantages. For almost all types of malignancy, the presence of cancer within regional lymph nodes portends a worse prognosis for patients, as a harbinger of systemic cancer spread. The accuracy of the assessment of the regional lymph node basin can be increased with either focused evaluation of the most at-risk lymph nodes (i.e., sentinel lymph node biopsy) or thorough sampling of a large number of nodes (i.e., lymphadenectomy). Accuracy of cancer staging, for example in colorectal cancer, is oftentimes increased through the sampling of a sufficient number of lymph nodes. The threshold for quality assurance through adequate lymph node sampling has been established for surgeons who perform colorectal cancer resections, however, that well-defined performance metric is not common to all types of resection and all types of cancer.¹³²⁻¹³⁵

For patients with bulky involved regional lymph nodes, the benefits of node removal are not likely prognostic. In selected patients, removal of these lymph nodes may provide some palliation from local symptoms. The role of "prophylactic palliation" or removal of lymph nodes, which may develop and cause local problems is less clear. For example, in melanoma or rectal cancer, eliminating all of the regional lymph nodes in the setting of positive microscopic nodal burden decreases the potential of future development of bulky, symptomatic nodes.^{128,136-138} The therapeutic benefit of avoiding local recurrence in a subset of the operative population needs to be balanced against the potential adverse effects of lymphadenectomy. For many nodal basin sites, the adverse impact of interrupting lymphatic flow can have significant deleterious effects on patients following lymphadenectomy, including lymphedema, paresthesias, and even development of secondary malignancies, such as angiosarcoma (Stewart-Treves syndrome).¹³⁹⁻¹⁴²

In general, lymphadenectomy is an important aspect of surgical cancer care when any of the following criteria are met: (1) removal of regional lymph nodes will provide important information to either guide adjuvant therapy decisions or provide prognostic clarity (e.g., colon cancer, gastric cancer); (2) lymphadenectomy can eliminate a predictably involved site of disease involvement which can lead to local regional complications in the setting of nodal recurrence (e.g., rectal cancer, esophageal

cancer); (3) removal of at-risk lymph nodes is a minor adjunct of the procedure for primary tumor removal (e.g., pancreatectomy). The extent of our operative management for cancer is likely to change as we learn more about the therapeutic benefit of regional nodal removal. Perhaps more strikingly, the prognostic information gained by evaluating a nodal basin is likely to diminish as our ability to profile tumors and their behavior becomes more dependent on genomic, proteomic, and other expression profiling.

Resection of Metastatic Disease

Outside the palliative setting, the indications for resection of metastatic disease are relatively narrow. Despite the growing awareness and increased frequency of resection for metastatic colon cancer, endocrine tumors, and gastrointestinal stromal tumors, the vast majority of patients with metastatic disease are not eligible for metastasectomy. Although it is important to recognize the diverse spectrum of presentations for malignant disease and to be wary of absolute contraindications against surgical management of metastases, several general principles do apply to the overwhelming majority of patients with metastatic disease.

Complete elimination of all sites of disease is generally associated with dramatically improved survival compared to incomplete resection. In addition, the outcomes for patients with incompletely resected disease are frequently comparable to outcomes for patients who underwent no resection at all.^{108–110,143–145} For these reasons, resection or ablation of all sites of disease is a common requirement when making a decision to proceed with resection of metastatic disease. This principle applies to patients with primary tumors in place as well; therefore, patients with unresectable primary tumors are generally not eligible for curative intent resection of their metastatic sites.

The behavior or biology of an individual's cancer may suggest a less aggressive phenotype and warrant consideration of metastasectomy. Oftentimes characteristics of favorable cancer biology are associated with improved survival outcomes following resection. A prolonged period of progression-free survival (PFS) or DFS is commonly associated with improved outcomes following resection of metastatic disease.^{143–145} Progression of metastatic sites while receiving first-line systemic chemotherapy is often a harbinger of early systemic failure among patients undergoing resection of metastatic disease.^{146,147} As systemic chemotherapy has grown more effective over the last decades, the impact on tumor progression and control of systemic disease has led to increased opportunities for resection of metastatic sites. This concept has been most plainly demonstrated in the context of hepatic colorectal metastases. The frequency of hepatectomy in that setting has increased in harmony with the increased effectiveness and availability of both cytotoxic and targeted chemotherapy agents.¹²² Surgical management of metastatic disease may increase in frequency for other diseases as we develop more effective systemic therapy options.

Cancer-Related Surgical Outcomes

The short-term outcomes for surgical patients commonly include metrics, such as complication rates, length of stay, mortality rate, and overall survival (OS). These metrics are certainly important measures of quality and efficacy for patients undergoing operations for cancer. Similar to other surgical specialties, cancer-related surgery also carries specific outcome measures, which are particularly relevant to these clinical scenarios. Understanding these metrics is critical to balancing risk and benefit for individual patients as well as for evaluating the role of new therapeutic strategies and approaches.

Disease Recurrence

Many surgical specialties are directed at the eradication of a tangible, anatomically identifiable lesion. Peripheral and coronary vascular bypass, gastroesophageal fundoplication, and parathyroidectomy are all measured by how effectively the treatment eliminates the arterial plaque, gastroesophageal reflux, or hyperparathyroidism. Early recurrence of the condition suggests a failure of therapy or poor patient selection for the procedure. Disease recurrence is also a critical measure of the effectiveness of surgical therapy for cancer patients.

A prerequisite for disease recurrence as a measure of outcome is the initial eradication of all visible cancer. Recurrence can be measured by development of symptoms, physical examination, radiographic evaluation, biochemical evaluation, or operative exploration. Unique to the practice of surgery for cancer patients is the distinction between locoregional and distant disease recurrence. Locoregional recurrence is typically defined as recurrence in the resection bed or region of the draining regional lymph nodes. Distant recurrence is typically defined as occurrence of malignant cells outside of the

initial primary tumor and lymphadenectomy resection field.

Although resection is traditionally considered a means to achieve locoregional control, and adjuvant systemic therapy is employed to control distant disease recurrence, a decision to proceed with an operation should consider how the operation impacts both locoregional and distant recurrence. A well-performed, radical, margin-negative operation can only lead to prolonged DFS if it is performed with appropriate patient selection. This distinction is the underpinning behind the approach for patients with small-volume metastatic disease in the setting of pancreatic adenocarcinoma, gastric cancer, or biliary tract cancers. Many patients, when faced with this scenario, will ask their surgeon, “Why can’t you just take out all of it?” Patients with easily resectable, distant disease are poor candidates for resection not because they cannot be rendered free of all visible disease but rather because the findings of metastases are highly predictive of early distant disease recurrence even if local control can be achieved. The trade-off for a short period of DFS after a radical operation is the chance at a more prolonged PFS or OS with the immediate initiation of effective systemic chemotherapy.

Progression-Free Survival

For patients who cannot have all visible tumor resected due to locally advanced disease or metastases, PFS is an important measure for subsequent therapy. The propensity for a treatment to control, but perhaps not eliminate, a measurable volume of tumor is the critical measure for defining the effectiveness of that therapy. For many types of cancer, PFS is a reliable surrogate for OS.^{148,149} Typically, when patients experience disease progression while receiving a particular regimen of systemic therapy, the treating physician will consider initiating the next line of systemic treatment.

Radiographic progression of measurable lesions is measured by a well-defined set of criteria referred to as RECIST or modified RECIST criteria. Response Evaluation Criteria in Solid Tumors (RECIST) was developed in 2000 and subsequently modified in 2009 as a system for measuring tumor response or progression.¹⁵⁰ These criteria are commonly employed in clinical trials as a standardized way to determine when a tumor has progressed on therapy. A simplified description of the criteria is included in Table 14-10. This strategy requires the upfront identification of index lesions, which are measurable radiographically. RECIST has proven to be a useful measure of potential treatment benefit in phase II clinical trials. Although useful in clinical trials, stringent application of RECIST measures of progression is not as readily used outside trial settings. Even small changes in the one-dimensional measurements or characteristics of measurable lesions may be considered evidence for clinical progression and justification for a change in treatment course.

Return to Intended Oncologic Treatment

A novel measure for the quality of surgical management of cancer patients is return to intended oncologic treatment (RIOT).¹⁵¹ This metric considers the place that resection holds in the multidisciplinary care of a cancer patient. Although surgical resection is required for a curative intent pathway for the majority of solid tumors, important oncologic adjuncts such as adjuvant chemotherapy, radiotherapy, and maintenance hormonal therapy can reduce the chances of recurrence and prolong survival for many patients. Delays or disqualifications due to operative adverse events may negatively impact the overall outcomes of patients. An important element in the assessment of the quality of cancer care is the ability for a health system to deliver all of the treatment modalities demonstrating benefit for a particular malignant condition. Recognizing that the definitive resection of a cancer is part of a larger treatment strategy is one of the important considerations for assessing surgical outcomes for patients with cancer.

Table 14-10 Common Criteria Used to Determine Therapy-Related Progression

Recist Category	Abbreviation	Definition
Complete response	CR	Disappearance of all target lesions
Partial response	PR	30% decrease in the sum of the longest diameter of target lesions
Progressive disease	PD	20% increase in the sum of the longest diameter of target lesions
Stable disease	SD	Small changes not meeting above criteria

The Role of Radiation Therapy in Cancer Management

Surgery is complemented by the modality of radiation therapy as part of a multimodal approach for many types of cancer. Like surgery, radiotherapy is typically focused on locoregional disease control. For that reason, many of the same principles apply to surgery and radiation oncology, such as patient selection, recognition of the behavior or tumor biology for a particular patient and cancer, and assessment of both short-term and long-term toxicities of therapy.

Mechanisms of Radiation Delivery

Energy emitted from a source travelling through space is termed “radiation.” As the energy passes through materials it interacts with those substances in one of two forms: photons or freely propagating particles. Photons are packets of electromagnetic fields travelling through space at the speed of light. The shorter the wavelength of the photon the greater the frequency of the oscillation and the higher the energy contained within the photon packet. Lower-energy photons make up the energy in visible light and only interact with the surfaces of objects. Higher-energy photons are used in diagnostic and therapeutic radiology and can pass through tissues to interact with deeper material and either reveal or impact underlying structures. Freely propagating particles carrying kinetic energy can be protons, electrons, or alpha-particles. These charged particles interact with other charged particles as they travel along their path. As photons or charged particles interact with biologic materials within the target area in the setting of therapeutic radiation, the interactions lead to ionization and subsequent biologic damage.

Linear accelerators (linacs) are the most common means for generating radiation in a manner allowing focused delivery of energy to a target tissue. Linacs can be used to generate either photon radiation or electron particles to be used as the ionizing agent. The linac uses oscillating electric fields to accelerate electrons toward a metal target converting the electron beam into a spray of photons. The photons are focused through filters and shaping elements to sharpen the beam of energy being delivered. A higher energy level of the photons travelling through the shaping process will lead to a higher level of energy delivered to the surface of the treatment target. As the photon beam travels across distance through a material, the dose will attenuate as the depth of penetration increases. Photons with higher energy penetrate more deeply into any given material and maintain the energy level for a greater distance. As this ionizing radiation travels through tissues, the photons deposit energy into the materials through which it passes. The total amount of energy delivered to a biologic system is measured in terms of joules per kilogram. The dose corresponding to the amount of energy delivered is expressed in terms of Gray (units of dose).

Tissue Response to Radiation

The therapeutic effects of radiation are contingent on the damage caused to the cells through which the ionizing radiation beam passes. The mechanism of action of cellular damage can be categorized into direct and indirect effects of radiation (Fig. 14-6). Both effects lead to the damage of DNA molecules. The direct effect of ionizing radiation is ionization of DNA molecules and the downstream effects of the damage to this critical cellular molecule. The indirect effect of ionizing radiation is best exemplified by the radiolysis of water molecules leading to the generation of free radicals. Free reactive species interact with DNA molecules causing indirect damage. The majority of total DNA damage is from this second, indirect effect. The proportional relationship between oxygen tension within tissues and the resultant damage caused by ionizing radiation is termed the *oxygen effect*.¹⁵² The phenomenon is explained by the capacity to generate a greater concentration of free radicals in oxygen-rich tissues than in hypoxic environments.

Figure 14-6. The mechanism of action of cellular damage can be categorized into direct and indirect effects of radiation.

Ionizing radiation can lead to multiple types of DNA damage: cross-linking of two DNA strands, loss of a DNA base or entire nucleotide, and breakage of the sugar-phosphate backbone.¹⁵³ Many of these types of damage are actually a failed attempt to eliminate unpaired electrons resulting from free radical generation. The mammalian cell has multiple DNA repair mechanisms operating with remarkable fidelity under typical conditions. In the setting of therapeutic radiation delivery, the DNA disruption is either too complex or too widespread to allow for normal mechanisms of repair. The generation of flawed versions of the original DNA molecule can lead to ineffective mitosis and failed cell division. Many cancer types are characterized by deficits in the DNA repair mechanism process.^{154,155} When these processes function suboptimally, the impact of radiation-induced damage can be more potent on the mutated cancer cells than on the DNA-repair intact nonneoplastic cells. Disruption of DNA synthesis by fluoropyrimidines such as 5-fluorouracil and capecitabine likely contributes to the therapeutic benefit of combining these agents to radiation. Fluoropyrimidines interfere with the capacity of cellular DNA repair mechanisms to correct DNA lesions induced by ionizing radiation.

Of course, ionizing radiation is relatively nonselective in terms of its deposition of energy packets into the tissues it traverses. Both normal and neoplastic cells are targets for the effects of radiation if the tissues lie in the beam of delivery. Different types of normal tissues demonstrate different levels of sensitivity to radiation. Breast tissue, intestinal mucosa, stem cells, lymphocytes, and bone marrow cells are considered radiosensitive based on their response to a given dose of radiation. Conversely, muscle cells, large arteries and veins, the heart, and neurons are considered more radioresistant based on the relatively low degree of cell death induced by radiation. Given a high enough radiation dose, nearly any malignancy can be destroyed. One of the key challenges of radiation therapy treatment planning is balancing the cytotoxic dose delivered to a given tumor with the impact that treatment will have on surrounding tissues. The therapeutic ratio is relationship between tumor killing and normal tissue complication rates.

Strategies to broaden the therapeutic ratio have focused on both increasing effective tumor killing and limiting the toxicity to normal tissues associated with a given dose of radiation. Approaches for increasing effective tumor killing include the use of radiosensitizers, preoperative radiation in a high oxygen tension environment, and fractionation. Fractionation is the division of a total therapeutic dose of radiation into multiple radiation treatments generally given daily. The biologic impact of dividing the total treatment dose is related to several cellular behaviors within the treatment field ([Table 14-11](#)). Fractionation increases the effectiveness of a radiation dose by allowing for *reoxygenation* and cell cycle *redistribution* within the tumor. Alternatively, approaches for reducing normal tissue toxicity include rotating gantry delivery systems using multiple beams reaching a single point via different routes through normal tissue, collimation allowing delivery of a narrow beam of energy, and fractionation. Fractionation decreases normal tissue toxicity by allowing initiation of DNA *repair* mechanisms and by a compensatory increase in cell proliferation in tissues such as stem cells in response to injury. The injury-induced increase in cell proliferation is termed *repopulation*. Since repopulation does not typically start until 4 weeks of radiation injury, most treatment plans are kept short to avoid tumor repopulation.

Understanding the deleterious effects of ionizing radiation on normal tissues is critical to understanding the therapeutic ratio for any radiation treatment plan. Desired cytotoxic effects on tumors are accompanied by undesirable cytotoxic effects on normal cells. Typically, treatment plans are developed to allow for the maximum tolerated dose (MTD) to be delivered to the structures within the treatment field. The MTD is based on the radiation tolerance of each structure or tissue type within that field. Plans incorporating shielding or avoidance of radiosensitive normal tissues can lead to safer and

more effective therapy. Although radiosensitive cells generally have a lower tolerance dose than radioresistant cells, this principle does not always hold true. The early and late effects of ionizing radiation may not be wholly determined by the degree of cell killing. Downstream effects, such as compensatory proliferation, cytokine-mediated responses, and radiation-induced gene expression can lead to undesirable tissue effects within the treatment field.¹⁵⁶

An important, although relatively uncommon, normal tissue effect of therapeutic radiation is the development of a second cancer. Approximately 20% of these second malignancies are leukemias. The majority of radiation-associated tumors are solid malignancies arising in the treatment field. These cancers typically develop many years after the original treatment. The increasing number of patients surviving disease free after an initial radiation treatment course may lead to an increasing number of these late second cancer events. Children and immunocompromised adults are more likely to develop second cancers.¹⁵⁷ Importantly, the risk of developing a second cancer within the radiation field is relatively low. In clinical scenarios where the benefit of therapeutic radiation is clearly demonstrated, the incidence of second malignancies does not generally skew the risk/benefit assessment against therapeutic radiation. However, an awareness of the potential for the development of a second cancer is critical for those who care for long-term cancer survivors.

Table 14-11 The Biologic Impact of Dividing the Total Treatment Dose is Related to Several Cellular Behaviors Within the Treatment Field

Biologic Principle	Therapeutic Effect	Tissue Response During Treatment Interval
Reoxygenation	Increase tumor killing	Remodels tissue to increase oxygen tension within tumor leading to reduced radiation resistance
Redistribution	Increase tumor killing	Greater fraction of cells in the radiosensitive S-phase of the cell cycle
Repair	Reduce normal tissue effects	DNA repair mechanisms of normal cells activated
Repopulation	Reduce normal tissue effects	Increased cell proliferation in response to radiation-induced injury

Radiation Therapy Delivery Modalities

Ionizing radiation can be delivered to an intended treatment area in a number of ways. The choice regarding the proper treatment modality includes decisions regarding the timing of radiation, the use of concurrent chemotherapy, and the delivery system for the radiation energy. Just as with surgical therapy, the primary determinant for all of these decisions is the intent of any radiation treatment plan. Therapeutic radiation can be employed as a part of a nonsurgical definitive treatment plan, as a palliative therapy, or as a means to complement the locoregional control of a surgical resection.

Radiation Treatment Approaches

Perioperative radiation therapy with or without chemotherapy sensitizers is commonly employed for tumors, such as rectal cancers, gastroesophageal cancers, and soft tissue sarcomas.^{158–160} When surgical therapy is combined with radiation and chemotherapy, this is often referred to as *trimodality* therapy. In these scenarios, radiation provides an additional element of local control by treating potential postsurgical residual disease in the tumor bed and lymphatic system. Preoperative radiation is generally preferred over postoperative radiation for several reasons. The normal tissue toxicity associated with any radiation treatment is largely within a planned field of resection when radiation is delivered preoperatively. Radiation delivered postoperatively is delivered entirely to a healing surgical bed. Additionally, treatment of a target field with an intact vascular supply and associated increased oxygen tension, theoretically enhances the indirect effects of the radiation energy. In clinical settings where the tumor is large or abuts major structures, such as major blood vessels, nerves, or bony structures, the reduction in size of a tumor may allow for preservation of critical structures and their function.

Chemotherapy is often combined with radiation as a definitive therapy for cancers that are either unresectable or exquisitely radiosensitive. Patients with anal cancer can avoid an abdominoperineal resection the majority of time due to the extremely high complete response rates of combined chemoradiotherapy.¹⁶¹ Locally advanced cancers such as pancreas adenocarcinoma or esophageal cancer may be treated with *concurrent chemoradiation* in order to alleviate local symptoms and limit the impact of local progression.

Definitive radiation therapy is not commonly employed for these locally advanced cancers. A more typical application of radiation alone is in the setting of certain small, radiosensitive cancers such as prostate cancer or nonmelanoma skin cancers.¹⁶² Cutaneous tumors in sensitive areas such as the face or head are good candidates for this approach in order to avoid the need for significant soft tissue

reconstruction. Patients with multiple high-risk comorbid factors or frailty may be good candidates for definitive radiation in order to avoid general anesthesia or prolonged inpatient recovery.

Radiation Therapy Delivery

The systems and technology used to generate and focus photons and electrons toward a target field can vary based on the requirements of each clinical scenario. Over the past several decades, techniques have advanced to generate a more focused beam of photons with increased delivery to target tissues and reduced collateral injury to normal tissue.

External beam radiation therapy is the most commonly employed therapeutic radiation strategy. Multiple angles of approach are used to deliver multiple beams of radiation to a target region. Modifiable factors with this approach include the angles of beam delivery, the shape of the beam, and the intensity of each beam. The radiation oncologist can adjust these factors to maximize the radiation dose focused on the target tissue while minimizing the effect on nearby, associated radiosensitive tissues. Patients undergo *simulation* as an early step in treatment planning. Contemporary simulation is typically performed with CT scan guidance. During this process, a patient undergoes a CT scan during which the radiation oncologist identifies the intended isocenter within target area. Using an integrated laser system to align the isocenter with sites on the patient surface, the radiation oncologist places tattoos to ensure reproducible, accurate beam alignment for future treatments. Patients typically undergo radiation treatment for 5 days a week for up to 6 weeks. *Intensity modulated radiation therapy* (IMRT) is an enhanced version of external beam therapy. IMRT uses mechanical devices or multiple beam integration to adjust the intensity within each beam in order to account for irregular patient surfaces or sensitive structures near the treatment region. By modifying the intensity within the beam, a more homogeneous dose distribution can be achieved within the target area.

Stereotactic body radiation therapy (SBRT) is a more specialized delivery system used for patients with brain tumors, lung cancer, and liver tumors. The applications of this technique are rapidly evolving as the expertise within the radiation oncology community grows. SBRT relies on precise motion control, high degrees of quality insurance, hypofractionation (commonly 1 to 5 treatments), and a relatively high dose per fraction to deliver a potentially ablative dose to the target area. Whereas conventional external beam radiotherapy may deliver a dose of 45 to 60 Gy over a course of 25 fractions (approximately 2 Gy per fraction), SBRT delivers 7 to 15 Gy per fraction with a lower number of total fractions. This technique has the potential to be a more definitive therapeutic option than conventional radiotherapy in light of the ablative intent of the treatment.

The use of radioactive implants, or *brachytherapy*, is common in the treatment of prostate and gynecologic cancers. Radioactive seeds can be placed either directly into the tumor (interstitial therapy) or within catheter-containing applicators placed in the vicinity of the tumor bed (intracavitary therapy). Intracavitary therapy has been developed as a potential adjuvant therapy for patients following resection of soft tissue sarcoma or partial mastectomy in the setting of breast conservation therapy.¹⁶³ The use of intracavitary therapy in these clinical settings is being explored but has certainly not achieved widespread acceptance.

In addition to intraoperative placement of radiation delivery applicators following resection, surgeons have assisted with radiation delivery through the use of *intraoperative radiation therapy*. In select environments where a specialized intraoperative irradiator is available, radiation is given directly to the tumor bed where incomplete marginal resection has been performed. The radiation is delivered in a single fraction of 10 to 15 Gy in combination with more traditional perioperative external beam radiation. The most common clinical applications for this technique have been in the treatment of pelvic and retroperitoneal tumors such as recurrent rectal cancer and retroperitoneal sarcoma.

The Role of Chemotherapy in Cancer Management

The use of chemotherapy as a modality in the treatment of cancer is almost universal and its efficacy is based on systemic treatment of primary and metastatic cancer. Unlike surgical resection or radiation therapy, the goal of chemotherapy is not necessarily localized or locoregional but systemic cancer treatment.

The setting in which chemotherapy is given can be defined as neoadjuvant, conversion, adjuvant, or palliative, dependent on the goals of the planned treatment course. Neoadjuvant chemotherapy is administered prior to a planned curative surgical resection. The primary or metastatic tumor is considered technically resectable at baseline but due to oncologic concerns of aggressive tumor biology a period of chemotherapy is used. An example of neoadjuvant chemotherapy is in the treatment of

advanced gastric cancer. The MAGIC trial for resectable gastroesophageal cancer included a treatment arm where patients with either node positive or locally advanced (by T tumor stage) gastric cancer were treated with a short course of chemotherapy prior to curative gastrectomy.¹⁶⁴ The potential benefits of neoadjuvant chemotherapy is to treat micrometastatic disease not seen on preoperative imaging, improve tumor-related symptoms, to allow for a period of time where metastatic disease can present precluding unwarranted surgical resection, and an in vivo method of determining tumor chemosensitivity. Conversion chemotherapy is also administered prior to surgical resection but the baseline tumor is considered unresectable, typically due to technical reasons, unlike in the neoadjuvant setting. An example of conversion chemotherapy is the administration of systemic chemotherapy to patients with metastatic colorectal liver metastases where upfront surgical resection is precluding by a sufficient future liver remnant.^{165,166} The goal of conversion chemotherapy is to downsize the baseline tumor allowing a safe curative resection. Adjuvant chemotherapy is administered in the postoperative setting after the primary or metastatic tumor is surgically resected. This is perhaps the most common setting of chemotherapy administration. Palliative chemotherapy is the setting defined as unresectable primary or metastatic cancer where the goal of chemotherapy is prolongation of life and not necessarily conversion to a curative resection.

The choice of systemic chemotherapy regimens is oftentimes tumor specific and is based on demonstrated efficacy in large phase III randomized controlled clinical trials. Table 14-12 lists the most commonly administered chemotherapy regimens, the presumed mechanism of action, and the applicable cancers treated.

The increasing knowledge of cancer genetics and biology has generated potential new targets for systemic therapeutic regimens ushering in potential individualized cancer treatments. The best example of a genetic abnormality with a systemic therapy specific for a molecular target is the BCR-ABL chromosomal translocation seen in patients with chronic myelogenous leukemia (CML).¹⁶⁷ The BCR-ABL fusion protein is a dysregulated tyrosine kinase that has a causal role in the development of CML and serves as the target for a new class of molecular inhibitors, tyrosine kinase inhibitors. The use of imatinib mesylate in CML has served as a prototype for the development of molecular target agents in other cancers, including gastrointestinal stromal tumor.¹⁶⁸ Unfortunately, most tumors, including the most common types, are genetically complex and do not offer a single target that serves as the critical inhibition point for cancer cell death.

Lack of single, molecular targets has led to the development of molecular targeted agents aimed at inhibition of pathways. An example of such a druggable pathway is the VEGF and its receptor (VEGFR). The VEGF pathway is an important regulator of physiologic and pathologic angiogenesis and is thought to promote tumor cell growth through increased vascular permeability, migration, differentiation of endothelial cells, and mobilization of bone marrow-derived endothelial cell precursors.¹⁶⁹ Overexpression of VEGF and/or VEGFR occurs in most common types of cancers and is associated with worse tumor presentation and outcome measures.¹⁷⁰⁻¹⁷² In 2004, the Federal Drug Administration approved bevacizumab, a humanized murine monoclonal antibody directed against VEGF, for the treatment of metastatic colorectal carcinoma.¹⁷³ Subsequent approval of sunitinib, sorafenib, and axitinib, three molecular targeted agents with activity against tyrosine kinase in addition to VEGF for renal cell carcinoma and HCC has established targeting pathways as a viable target for cancer therapeutics.¹⁷⁴⁻¹⁷⁷

Table 14-12 Common Systemic Therapeutic Agents for the Treatment of Cancer

Drug Name	Mechanism of Action	Relevant Cancers
Ziv-aflibercept (Zaltrap)	Fusion protein binding VEGF-related ligands	Colorectal cancer
Anastrozole (Arimidex)	Nonsteroidal aromatase inhibitor selectively blocks estrogen production	Breast cancer
Bacillus Calmette–Guérin (TICE BCG, TheraCys), BCG	Immunostimulant/vaccine; induces localized cellular immune response	Bladder cancer
Bevacizumab (Avastin)	Recombinant humanized monoclonal antibody binds VEGF	Colorectal cancer, NSCLC, RCC
Bleomycin (Blenoxane), Bleo	DNA strand breaks	Germ cell tumors, Hodgkin disease, squamous cell cancers, melanoma, ovarian cancer, Kaposi sarcoma
Capecitabine (Xeloda)	Oral antimetabolite prodrug	Breast cancer, colorectal cancer, head and neck squamous cell cancer
Carboplatin (Paraplatin), Carbo, CBDCA	DNA intrastrand and interstrand cross-links	Ovarian cancer, testicular cancer, squamous cell cancers – head, neck, cervix, lung cancer
Carmustine (BiCNU), BCNU, bis-chloronitrosourea	Alkylating agent	Melanoma, stomach cancer, colon cancer, liver cancer, brain tumors, multiple myeloma, Hodgkin disease, lymphoma, breast cancer
Cetuximab (Erbix)	Recombinant humanized monoclonal antibody targeting EGFR	Colorectal cancer, head and neck cancer
Cisplatin (Platinol) – cDDP, DDP, cisplatinum, cis-diamminedichloro-platinum (II)	DNA intrastrand and interstrand cross-links	Lymphoma, testicular, ovarian, gastric cancer
Docetaxel (Taxotere), RP- 56976	Inhibits depolymerization of tubulin in the spindle apparatus	Metastatic breast cancer, NSCLC
Doxorubicin (Adriamycin, Rubex), Adria, hydroxydaunorubicin	Anthracycline induces free radical formation, altered mitochondrial function, and topoisomerase II inhibition	Breast carcinoma, sarcomas, pediatric solid tumors, Hodgkin disease, non-Hodgkin lymphomas, ovarian cancer
Epirubicin (Ellence)	Anthracycline induces free radical formation, altered mitochondrial function, and topoisomerase II inhibition	Breast cancer
Erlotinib (Tarceva)	Targets EGFR	NSCLC, pancreatic cancer
Etoposide (Vespid), VP-16, epipodophyllotoxin; also available as etoposide phosphate (Etopophos)	Plant alkaloid; topoisomerase II inhibitor	Germ cell tumors, SCLC, lymphomas, AML, brain tumors, non-SCLC, breast cancer, ovarian cancer, lymphomas
Everolimus (Afinitor)	mTOR inhibitor	Breast cancer, PNET, RCC, renal angiomyolipoma, TSC
Exemestane (Aromasin)	Steroidal aromatase inhibitor	Breast cancer
Floxuridine (FUDR), FdUR, fluorodeoxyuridine	Pyrimidine antimetabolite nucleotide analog	GI adenocarcinomas metastatic to the liver
5-Fluorouracil (Adrucil, Efudex), 5-FU	Pyrimidine antimetabolite inhibitor of thymidylate synthase	Colon, rectum, gastric, pancreas, breast carcinomas, liver metastases from GI tumors, cutaneous neoplasms, disorders
Fulvestrant (Faslodex) estrogen receptor antagonist	Estrogen receptor degradation	Breast cancer
Gemcitabine (Gemzar)	Antimetabolite nucleoside analog	Pancreatic adenocarcinoma, NSCLC, breast cancer, bladder cancer
Hydroxyurea (Hydrea) – hydroxycarbamide	Antimetabolite inhibitor of ribonucleotide reductase	CML, myeloproliferative disorders, melanoma, refractory ovarian carcinoma, squamous cell carcinoma – cervix, head, neck
Ifosfamide (Ifex)	Alkylating agent	Germ cell tumors, sarcomas, lymphoma, Hodgkin disease, breast cancer, ovarian cancer
Interferon-alpha (IntronA, Roferon)	Biologic response modifier	Melanoma, multiple leukemias and lymphomas
Interleukin-2 (Proleukin) – aldesleukin, IL-2	Cytokine stimulates lymphocytes and an inflammatory cytokine cascade	Renal cell cancer, metastatic melanoma, acute myeloid leukemia

Peginterferon alfa-2b (Sylatron)	Pleiotropic cytokine	Melanoma
Ipilimumab (Yervoy)	Human CTLA-4–blocking antibody	Melanoma
Irinotecan (Camptosar) – CPT-11	Topoisomerase I inhibitor	Colon cancer, lung cancer, ovarian cancer, lymphoma
Lapatinib (Tykerb)	EGFR and HER2 tyrosine kinase inhibitor	Breast cancer
Letrozole (Femara)	Nonsteroidal aromatase inhibitor	Breast cancer
Leuprolide acetate (Lupron) – leuporelin acetate	Gonadotropin-releasing hormone agonist chronically inhibits pituitary gonadotropin release	Prostate cancer, breast cancer, endometriosis
Melphalan (Alkeran), l-PAM, l-phenylalanine mustard, l-sarcolysin	Alkylating agent	Myeloma, ovarian carcinoma
Methotrexate (Mexate, Folex, others) – MTX, amethopterin	Antifolate antimetabolite inhibits dihydrofolate reductase	Breast and bladder cancer, squamous cell cancers, sarcomas
Mitomycin C (Mutamycin)	Inhibits DNA and RNA synthesis	Stomach, pancreas, breast, lung adenocarcinoma
Mitotane (Lysodren), o,p'-DDD	Adrenocortical cytotoxin	Adrenal cortical carcinoma
Octreotide, octreotide long acting (Sandostatin, Sandostatin LA), l-cysteinamide	Synthetic peptide analog of somatostatin; hormonal inhibition of serotonin, insulin, glucagon, and gastrin	Carcinoid tumors
Oxaliplatin (Eloxatin)	DNA intrastrand and interstrand cross-links	Colorectal adenocarcinoma
Paclitaxel (Taxol, Onxol)	Inhibits depolymerization of tubulin in the spindle apparatus	Ovarian cancer, breast cancer, lung cancer, head and neck cancer, bladder cancer
Paclitaxel, protein bound (Abraxane)	Inhibits depolymerization of tubulin in the spindle apparatus	Breast cancer
Panitumumab (Vectibix)	Recombinant, fully humanized monoclonal antibody competitively binds to EGFR	Colorectal cancer
Pemetrexed (Alimta)	Antimetabolite; inhibits folate-dependent enzymes thymidylate synthetase, dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase	Mesothelioma, NSCLC
Pertuzumab (Perjeta)	HER2/neu receptor antagonist antibody	Breast cancer
Regorafenib (Stivarga)	Small molecule inhibitor of membrane-bound and cellular kinases	Colorectal cancer
Sorafenib (Nexavar)	Inhibits VEGFR and PDGFR kinases as well as RAF/MEK/ERK kinases	Hepatocellular cancer, renal cell carcinoma
Streptozocin (Zanosar)	Alkylating agent	Neuroendocrine tumors, pancreatic carcinoma, Hodgkin disease
Sunitinib malate (Sutent)	Inhibits PDGFR and VEGFR	Renal cell carcinoma, GIST, pancreatic neuroendocrine tumors
Tamoxifen (Nolvadex)	Nonsteroidal antiestrogen	Breast cancer, melanoma, pancreatic cancer
Temozolomide (Temodar)	Atypical alkylator	Astrocytomas, gliomas, metastatic melanoma
Temsirolimus (Torisel)	mTOR inhibitor	Renal cell carcinoma
Thalidomide (Thalomid)	Antiangiogenic and immunomodulating agent	Renal cell carcinoma, metastatic melanoma, malignant gliomas
Topotecan (Hycamtin), hycamptamine	Inhibitor of topoisomerase I	Ovarian carcinoma, lung cancer, myeloid leukemias
Trastuzumab (Herceptin)	Genetically engineered humanized mouse monoclonal antibody against HER2/neu growth factor receptor	Breast cancer, gastric cancer
Vandetanib (Caprelsa)	kinase inhibitor	Thyroid cancer
Vemurafenib (Zelboraf)	Inhibits V600E serine–threonine and other kinases	BRAF+ melanoma
Vinblastine (Velban, Velsar, others), VLB, vincalukoblastine	Vinca alkaloid; inhibitor of tubulin polymerization and mitosis; G2-phase specific	Hodgkin disease, non-Hodgkin lymphoma, germ cell tumors, breast cancer
Vincristine (Oncovin, Vincasar), leurocristine, VCR	Vinca alkaloid; inhibitor of tubulin polymerization and mitosis; G2-phase specific	Hodgkin disease, lymphomas, acute leukemias, rhabdomyosarcoma, neuroblastoma, Wilms tumor
Vinorelbine (Navelbine), 5'-noranhydrovinblastine, NVB	Semisynthetic vinca alkaloid; inhibitor of tubulin polymerization and mitosis; G2-phase specific	Breast cancer, NSCLC

Staging (Traditional and Genetic)

Cancer staging is the process of determining the cancer burden within the body and the location. Staging describes the severity of an individual's cancer based on the magnitude of the original or primary tumor as well as on the extent of cancer spread via metastases. Understanding and properly staging cancer is important as it provides a common language for communication among providers and patients, is a prognostic marker of outcome, allows appropriate treatment decisions, and stratifies

patients for clinical trials.

There are four different types of staging: (1) clinical staging: based on physical examination, imaging tests, and appropriate biopsies, (2) pathologic stage: determined following surgical excision of cancer; both clinical and pathologic characteristics contribute to the pathologic stage, (3) neoadjuvant or posttherapy staging: following treatment with systemic chemotherapy or radiation therapy, relying on clinical and/or pathologic staging guidelines, and (4) restaging: the extent of recurrent disease following definitive therapy. The formal stage of a cancer does not change over time, even if the cancer progresses. A cancer that returns or demonstrates progression is still referred to by the stage it was given at first diagnosis. Restaged cancer is noted with a lower case “r” indicating a restaging designation.

Table 14-13 TNM Staging Based on AJCC and UICC Classification

T category describes the primary tumor	
Tx	Primary tumor cannot be evaluated
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1–T4	Size and/or extent of tumor
N category describes regional lymph node status	
Nx	Regional lymph nodes cannot be evaluated
N0	No regional lymph node involvement
N1–N3	Number and/or extent of lymph node involvement
M category describes distant metastatic disease	
M0	Absence of distant metastatic disease
M1	Distant metastasis

Tumor staging in most solid tumors is based on four main factors: (1) location of the primary or original tumor, (2) tumor size and/or extent of tumors, (3) lymph node involvement or spread, and (4) presence or absence of distant metastases. The TNM staging system developed by the American Joint Committee on Cancer (AJCC) and Union for International Cancer Control (UICC) is the most widely used system and is based on the extent of primary tumor (T), the extent of spread to lymph nodes (N), and the presence of metastases (M). [Table 14-13](#) demonstrates the general AJCC/UICC TNM staging system; specific staging systems have been developed for each individual malignancy. Once the T, N, and M individual stages are determined, they are combined, and an overall stage of 0, I, II, III, or IV is assigned.

In addition to utilizing the traditional AJCC/UICC TNM staging systems, genomic data have been recently incorporated to further fine tune and guide treatment decisions. The best-studied example is the use of genomic tests for breast cancer staging. In four externally validated, commercially available tests, genomic information is coupled with pathologic staging helping providers to determine the risk of recurrence of early-stage, estrogen-receptor–positive breast cancers, and the benefit of adjuvant chemotherapy. In addition, these genomic tests also have been validated in breast ductal carcinoma in situ to determine the risk of recurrence following resection, the risk of a de novo cancer developing in the same breast, and the benefits of adjuvant radiation therapy.¹⁷⁸ Unfortunately, similar genomic tests with proven clinical validation are lacking in other cancer subtypes and remain exploratory and useful only in a research setting at this time.

Screening

The development of the periodic health examination in the late 19th century by medical providers was the impetus linking cancer mortality to delay in diagnosis. In 1907, Dr. Charles Childe published the first book, *The Control of a Scourge, Or How Cancer is Curable*, detailing cancer as a linear carcinogenesis pathway that could be interrupted by identification of early warning signs and symptoms, thus eradicating cancer.¹⁷⁹ Although too simple, this publication and others led to the upsurge of a large-scale health campaign in the 1940s within the United States aimed at advocating early cancer detection programs, or cancer screening.

Technologic advances in screening and early detection are essential for progress in both the prevention and treatment of cancer, but incorporation of such advances to useful clinical practice is often challenging and requires careful consideration of all potential risks and benefits. For any screening test to be useful, three tenets of screening should be met: (1) a test must exist that will detect the

disease earlier than routine methods, (2) evidence must exist that earlier treatment leads to improved outcomes, and (3) benefits of screening must outweigh the risks associated with any subsequent diagnostic and therapeutic treatments.

The Canadian Task Force on the Periodic Health Examination and the United States Preventive Services Task Force (USPSTF) in [Figure 14-7](#) provide the basic analytical framework necessary to delineate the steps for evaluating the worth of a screening test.¹⁸⁰ The framework demands a clear identification of the population at risk that is to be screened. The importance of this starting point is due to the potential changing nature of the screened population and extrapolation of findings from a subset of patients to a general population. More importantly, the framework details the adverse effects of both screening and treatment of early-stage cancers. Because screening tests are performed on healthy individuals there is significant potential harm associated with a false-positive test. A recent meta-analysis determined that after 3 years of screening tests, a man's and woman's risk of obtaining at least one false-positive test was 60% and 50%, respectively.^{181,182} False-positive tests are a concern for three reasons. First, they have the potential to generate negative psychological consequences. Second, they can trigger a cascade of more invasive follow-up testing, which since the patient does not have cancer and can obtain no benefit, represents pure harm to the individual. Third, false-positive tests and the cascade of follow-up tests represent a significant burden to already strained healthcare resources.¹⁸³

Figure 14-7. Analytic framework for evaluating a screening test. (Adapted from Harris RP, Helfand M, Woolf SH, et al. Current methods of the US Preventative Task Force: a review of the process. *Am J Prev Med* 2001;20:21–35.)

Figure 14-8. A: With screening, the lead time in diagnosis prolongs survival even if death is not delayed. B: Screening is more likely to detect indolent or slow-growing cancers therefore giving a length bias where survival appears improved with screening but is secondary to the less aggressive tumor biology.

In addition to potential harms, at least two important biases, lead-time and length, need to be accounted for prior to advocating for a screening test. The intent of screening is to advance the date of diagnosis to an earlier point in time than it would otherwise been made. Therefore, lead-time refers to the amount of time between screen-detected and symptom-detected diagnosis ([Fig. 14-8A](#)). This lead-time in diagnosis appears to prolong survival in screened individuals, although mortality in this group may not actually be delayed, creating a lead-time bias. The use of 5-year survival rates to judge the efficacy of a cancer screening test must be used with caution. For example, the Mayo Lung Project used chest x-ray and sputum cytology as screening modalities in a randomized controlled trial and demonstrated that 5-year survival rates increased from 19% to 36% in the screened population. However, lung cancer mortality rates were not significantly different between the two groups indicating that although lung cancer was diagnosed sooner in the screened group no overall benefit was noted.¹⁸⁴

Length-time bias refers to the tendency of screening to detect cancers that are indolent and slower

growing because of a longer detectable preclinical phase compared with faster-growing, more aggressive forms of cancer (Fig. 14-8B). Consequently, in a group of screened individuals this phenomenon creates the appearance that screening is extending survival, when in fact extended survival is due to the more indolent nature of the cancers found in this group and not necessarily to the screening itself. Over diagnosis is one extreme form of length-time bias and can occur in two situations: (1) cancers that are so benign that they have virtually no growth potential and (2) cancers that grow so slowly that the person would die of another competing cause of death before the tumor generated symptoms. The classic indication of an over diagnosis bias is a rise in early-stage cancers coupled with a minor or even nonexistent decline in incidence of late-stage disease. An example of over diagnosis is seen in prostate cancer where although there is a decrease in the rate of late-stage disease, the absolute rate of decline makes up only a tiny fraction of the associated increase in early-stage disease. Thereby, there are more early cases being identified than late-stage cases being prevented.

4 Currently, population-based screening tests are available for the following cancers: cervical (Papanicolaou test), colon (colonoscopy, fecal occult blood test, flexible sigmoidoscopy, and double-contrast barium enema), breast (mammogram), and prostate (PSA test). The current recommendations for screening by the USPSTF and/or American Cancer Society are listed in Table 14-14.¹⁸⁵

Surveillance

Improving cancer survival rates have generated an increased focus on survivorship programs, or the care of the cancer patient following treatment. One of the goals of these follow-up care programs is the early detection of tumor recurrence and new primary cancers at a point where curative treatment is still possible. Unfortunately, due to the heterogeneity of cancer treatment and outcome measures there is a paucity of evidenced-based data concerning follow-up care, surveillance protocols, and secondary prevention measures for survivors of cancer. Currently, there are recommended guidelines for only two cancers, colorectal and breast, detailing survivorship programs.^{186,187}

Surveillance following curative resection of colorectal cancer is guided by the presumed risk of recurrence and functional status of the patient and is generally heightened in the first 4 years following surgery.¹⁸⁷ Current ASCO guidelines recommend the following: (1) a medical history, physical examination, and carcinoembryonic antigen (CEA) testing every 3 to 6 months for 5 years, (2) annual abdominal and chest imaging using computed tomography for 3 years, PET imaging is not recommend, and (3) surveillance colonoscopy approximately 1 year following surgery with repeat procedures every 5 years if no abnormal findings.

Table 14-14 Current Population-Based Screening Recommendations

Site	Recommendation
Cervical	Women, 21–65 years of age (Pap smear, every 3 years) or 30–65 years of age (in combo with HPV testing, every 5 years)
Colon	50–75 years of age (fecal occult blood testing-every year, flexible sigmoidoscopy-every 5 years, or colonoscopy-every 10 years) ^a
Breast	Women, age 50–74 years of age (biennial screening mammography) ^b or age 40 years and greater (biennial screening mammography) ^c
Prostate	Men, age 50 years and greater at average risk of prostate cancer once discussion of benefits and harms of test (PSA level) ^c USPSTF does not recommend routine prostate cancer screening

^aUSPSTF does not specify surveillance period.
^bUSPSTF recommendations.
^cAmerican Cancer Society recommendations.

The length of surveillance following breast cancer treatment corresponds to the risk of recurrence. As breast cancer recurrences can occur decades following curative treatment, current continual surveillance is recommended for at least 15 years.¹⁸⁶ Current ASCO guidelines also recommend the following: (1) history and physical examination every 3 to 6 months for the first 3 years, then every 6 to 12 months for the next 2 years, and then annually, (2) referral to genetic counseling for women at high risk for familial breast cancer syndromes, (3) mammography beginning 6 months after definitive radiation therapy, then annual mammograms following stability of mammographic findings, and (4) regular gynecologic follow-up.

Cancer Biostatistics

The driving force behind the maturation of an epidemiologic approach to oncology has been the incorporation of statistical analysis in modern medical research. This is no more evident than when discussing survival rates following diagnosis with cancer. The most common survival statistic is OS, which is typically defined as the time from diagnosis or treatment to death from any cause and is measured either as a median (months) or as a percentage over 5 years (5-year OS). Disease-specific survival (DSS) is similar to OS and is measured in months or in a 5-year percentage but where the end measure is death due to cancer, which is oftentimes difficult to ascertain retrospectively. PFS and time to progression (TTP) are commonly used to assess efficacy in cancer drug development. PFS is defined as time of treatment start (or randomization in randomized clinical trials) to the time of disease progression or death from any cause. Similarly, TTP measures the interval from time to treatment start but concludes at time of disease progression. Unlike PFS, deaths are censored from analysis in TTP calculations. Although, used interchangeably, PFS is likely more suitable to situations where a therapy or intervention can produce an adverse event directly leading to death. Whereas, TTP is more commonly used in clinical trials with high underlying patient comorbidity, where early patient death from nontreatment-related events could negatively skew the studied treatment effects. Other commonly used survival rates include DFS and recurrence-free survival (RFS). DFS is defined as the time from treatment to recurrence of disease either from the treated cancer or a new primary. RFS is defined as the time from treatment to recurrence of disease only related to the treated cancer and not a new primary. Again, both RFS and DFS can be measured in months or time interval percentage, commonly 3- or 5-year increments.

In a typical clinical trial or study, survival outcome data are represented as a Kaplan–Meier plot (Fig. 14-9). In constructing a Kaplan–Meier survival curve, the probability of surviving in a given length of time is calculated. For each time interval, survival probability is calculated as the number of subjects surviving divided by the number of patients at risk. Subjects who have died or dropped out are no longer considered part of the at-risk population and are removed from the denominator. Within the graphical representation of the plot, if a patient is removed or no longer participating in the study before the final outcome is observed, death in OS analysis, the patient is censored and a small vertical tick mark is seen. The most common statistical method comparing Kaplan–Meier estimates is the log rank test, which calculates the chi-square for each event time for each group and sums the results giving a *p*-value. In addition to the log rank test, median values of an outcome measure can be calculated from a Kaplan–Meier plot.¹⁸⁸

Figure 14-9. Kaplan–Meier survival curve of a hypothetical cancer. Median overall survival is plotted by the time in months of the median or 50% patient (*red line*). Deaths represent the step down lines in the curve. Censored events including lost to follow-up are represented by the vertical tick marks.

Clinical Trials

Clinical trials, in their purest form, are designed to observe outcomes of human subjects under “experimental” conditions controlled by the researcher. Prior to initiation of human clinical trials, preclinical investigations include the following animal studies: studying the treatment or drugs safety in animals at doses equivalent to human exposure, pharmacodynamics, and pharmacokinetics need to be completed. Pharmacodynamics is the study of what a drug or treatment does to the body, whereas pharmacokinetics is the study of the body’s effect on the drug.

The first studies done in human are phase I trials. These are usually open-labeled studies performed in a small number of “healthy” or “diseased” individuals with the intent on obtaining the MTD useful for further trials. The MTD is determined by dose escalation of the study drug or treatment and closely following patients for predetermined, dose-limiting toxicities or adverse events. Typically, there are no therapeutic end points including survival or progression included in phase I trials.

Phase II trials, also referred to as “therapeutic exploratory” trials, are usually larger than phase I trials, and are conducted in patients with the disease in question. They are designed to test safety, pharmacokinetics, and pharmacodynamics as well as providing preliminary data on optimal doses and frequencies for future phase III trials. Trial design can include a single arm with comparison to historical controls or a randomized design comparing the study drug or treatment directly with either placebo or a known drug or treatment. Usually the narrow scope of phase II trials prevents full approval for a study drug or treatment and requires validation in a phase III trial.

Phase III trials, are typically large-scale studies performed in a more diverse target population in order to confirm efficacy of earlier trials and to identify and estimate the incidence of common adverse events. The most common type of phase III trial is comparing the intervention of interest with either a standard therapy or placebo with a balance in treatment allocation typically through randomization. Another feature of phase III trial design is stratification, which balances study arms by ensuring that specific prognostic factors of presumed clinical importance are properly balanced in the arms of a clinical trial. Following drug or treatment approval, a phase IV trial may be completed. These trials also referred to as “postmarketing” studies are observational in nature and are aimed at identifying less common adverse reactions and evaluating cost and/or drug effectiveness in diseases, populations, doses similar to or markedly different from the original population. The results of phase IV studies can lead to new black box warnings and even withdrawal of the drug or treatment for safety reasons.¹⁸⁹

Chapter 15

Preoperative Risk Assessment

Pauline Park

Key Points

- 1 Preoperative risk assessment is critical to informing patients of the risk and benefits of surgical interventions.
 - 2 The development of postoperative complications drives patient mortality and higher health care costs. Interventions aimed at prevention and early recognition of complications may lower surgical risk.
 - 3 Consideration of patient-centered outcomes may appropriately determine that noncurative surgical intervention may be counter to the patient's true desires.
 - 4 National Surgical Quality Improvement Programs from the Veterans' Administration and the American College of Surgeons have examined large data sets in a data-driven approach to more finely characterize risk for mortality and complications.
 - 5 Specific comorbidities affect both the conduct of surgery and the outcome in ways that can be anticipated and addressed.
 - 6 Identification of patients at risk permits quality assurance monitoring and offers the opportunity to improve care with individual- and system-level interventions.
-

INTRODUCTION

1 The goal of preoperative assessment is to evaluate an individual's risk for postoperative adverse events and to deliberately incorporate that assessment into plans for surgical intervention. It forms the basis of the contract between the patient and the surgeon; both wish to predict future outcomes and to balance the risks and benefits of surgery. By synthesizing clinically available data, we can attempt to stratify and modify risk so that the equation will favor benefit, all the while prioritizing patient-centered goals of care.

Early landmark work in cardiac preoperative evaluation by Goldman et al.¹ clearly demonstrated that high-risk surgical patients could be identified through careful assessment of clinical history, physical examination, and laboratory data. This has been extended by further observations in specific types of surgery and in subgroups of patients with particular disease states. Granular, patient-level analyses using "big data" approaches have led to the development of targeted interventions aimed at reducing the risk of a given procedure for a given patient. Thus, preoperative evaluation has evolved to include not only prediction of risk but also consideration of potential proactive interventions at both the individual patient and system levels. Inclusion of patient values and desired outcomes completes the course of informed decision-making.

This chapter reviews the relevance of risk determination, examples of data-driven approaches to individualize risk prediction, clinical aspects of preoperative evaluation, guidelines for specific disease-related conditions, and future directions for prevention of complications and intervention should they occur. All of these should be considered in the context of selecting the best approach for each patient.

SURGICAL MORTALITY, COMPLICATIONS, AND PATIENT-CENTERED OUTCOMES

Mortality rates following surgery have continued to improve with innovations in surgical technique and advances in overall quality of medical care. Since the 1950s, large reductions in intraoperative mortality have been accomplished through anesthesiology-led initiatives championing safer operating room

protocols, continuous monitoring, and error reduction. By incorporating high-reliability processes into operating room routines, the overall mortality risk attributable to a general anesthetic has been reduced from 25 per million to 50 per million in the 1970s and 1980s to 1 per million to 5 per million.²

From the surgical standpoint, population-based mortality rate varies sharply with the extent of the procedure and patient age.³ Overall surgical mortality in the Nationwide Inpatient Sample decreased from 1.68% in 1996 to 1.32% in 2006.⁴ Substantial interhospital variation exists and underscores the possibility for additional opportunities for improvement. The Safety in Surgery Study evaluated a large cohort of general and vascular surgical patients at 128 VA and 14 academic hospitals between 2001 and 2004.⁵ The overall 30-day postoperative mortality ranged between 2.19% and 2.87% over the 3 years, with adjusted odds ratios varying between individual institutions (Fig. 15-1). Similarly, in a 7-day cohort study of noncardiac surgery in Europe, adjusted in-hospital mortality after surgery varied widely between countries (odds ratio = 0.44 to 6.22) when compared with the United Kingdom.⁶

In 2000, the Institute of Medicine suggested that preventable adverse events accounted for as many as 98,000 in-hospital deaths.⁷ The search for further improvement in surgical mortality has focused on reducing the incidence of postoperative complications. Surgical complications are strongly related to mortality,⁸⁻¹⁰ with the ability to rescue from postoperative complications an important factor in determining eventual outcome.¹¹ The 10 most common perioperative complications seen in the Patient Safety in Surgery Study hospitals included infectious, pulmonary, cardiac, renal, and venous thrombotic events (Table 15-1).

2 Postoperative complications are associated with increased health care costs and resource utilization. Average hospital costs may double following occurrence of a complication,¹² with variation in reimbursement exerting significant effects on both hospital profit and contribution margins.^{13,14} Postoperative complications are also strongly linked to hospital readmissions (Table 15-2),¹⁵ with a substantial number of complications identified only after initial discharge.¹⁶ As an example, approximately a quarter of colon resection patients are readmitted within 90 days, at an estimated cost of \$300 million annually.¹⁷

Figure 15-1. Variation in surgical mortality.

These circumstances influence both institutional and overall health care delivery. The overwhelming health care spending burden adds pressure to provide efficient, high-quality care. Hospital performances on quality measures are widely available on the Internet and mandated public reporting can easily affect market share and policy making. These system-level considerations only heighten the push toward population-based management of surgical care.

Nevertheless, the direct impact of postoperative complications on an *individual* patient's quality of life is critical. The consequences are often unrecognized by standard hospital-based review. In 2004, Clavien and Dindo proposed a complication grading scale based on the severity of intervention required to address a given complication, including the presence of associated disability (Table 15-3).¹⁸ This classification has been validated in a cohort of more than 6,000 patients, with subsequent evaluation showing 89% interrater agreement and correlation between perceptions by patients, nurses, and physicians.¹⁹ It is hoped that encouraging standardized complication grading will increase meaningful,

patient-centered outcomes reporting.

Table 15-1 Surgical Complications: Comparison of the 10 Most Frequent Perioperative Complications Between Private Sector and VA Hospitals

14 Private Sector Hospitals (n = 54,585)		128 VA Hospitals (n = 130,258)	
Perioperative Complication	%	Perioperative Complication	%
1. Superficial wound infection	3.6	1. Superficial wound infection	3.1
2. Failure to wean from ventilator for >48 hrs	2.9	2. Pncumonia	2.5
3. Urinary tract infection	2.8	3. Failure to wean from ventilator for >48 hrs	2.5
4. Pncumonia	2.2	4. Reintubation	2.0
5. Systemic sepsis	2.1	5. Urinary tract infection	2.0
6. Reintubation	1.8	6. Deep wound infection	1.6
7. Deep wound infection	1.2	7. Systemic sepsis	1.6
8. Wound dehiscence	1.1	8. Wound dehiscence	1.2
9. Acute renal failure	0.7	9. Cardiac arrest	0.9
10. Deep vein thrombophlebitis	0.7	10. Myocardial infarction	0.6

Adapted from Khuri SF, Henderson WG, Daley J, et al. Successful implementation of the Department of Veterans Affairs' National Surgical Quality Improvement Program in the private sector: the Patient Safety in Surgery study. *Ann Surg* 2008;248(2):329–336.

Table 15-2 Number of Surgical Readmissions by Readmission Reason

Reason for Readmission	Number of Readmissions	%
Gastrointestinal complication	45	28.6
Surgical infection	36	22.1
Failure to thrive/malnutrition	17	10.4
Wound complication	13	8.0
Genitourinary complication	8	4.9
Vascular complication	6	3.7
Pulmonary problem	6	3.7
Cardiac problem	5	3.1
Fever	4	2.5
Pain	3	1.8
Transplant complication	3	1.8
Neurologic problem	2	1.2
Other	15	9.2

Adapted from Kassin MT, Owen RM, Perez SD, et al. Risk factors for 30-day hospital readmission among general surgery patients. *J Am Coll Surg* 2012;215(3):322–330.

Table 15-3 Grading of Surgical Complications: Clavien–Dindo Classification

Grade	Definition
Grade I	Any deviation from the normal postoperative course without the need for pharmacologic treatment or surgical, endoscopic, and radiologic interventions Allowed therapeutic regimens are drugs as antiemetics, antipyretics, analgetics, diuretics, electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside
Grade II	Requiring pharmacologic treatment with drugs other than such allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included
Grade III	Requiring surgical, endoscopic, or radiologic intervention
Grade IIIa	Intervention not under general anesthesia
Grade IIIb	Intervention under general anesthesia
Grade IV	Life-threatening complication (including CNS complications) ^a requiring IC/ICU management
Grade IVa	Single organ dysfunction (including dialysis)
Grade IVb	Multiorgan dysfunction
Grade V	Death of a patient
Suffix “d”	If the patient suffers from a complication at the time of discharge (see examples in Table 15-2), the suffix “d” (for “disability”) is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication

^aBrain hemorrhage, ischemic stroke, subarachnoid bleeding, but excluding transient ischemic attacks.
CNS, central nervous system; IC, intermediate care; ICU, intensive care unit.
From Dindo D, Demartines N, Clavien PA. Classification of surgical complications: a new proposal with evaluation in a cohort of 6336 patients and results of a survey. *Ann Surg* 2004;240(2):205–213.

3 Finally, the recognition that a surgical admission may represent a turning point in the overall trajectory of a patient’s life refocuses the preoperative evaluation to look beyond the index hospitalization. In 2008, one-third of Medicare decedents underwent a surgical procedure during their last 12 months of life.²⁰ The preoperative discussion should address the patient’s understanding of the potential impact of surgical care and include expected quality-of-life outcomes. It is important to integrate patient-centered goals of care into treatment recommendations; an operation that does not prolong meaningful quality of life may be counter to the patient’s expectations of surgical care.

RISK STRATIFICATION

4 The goal of risk stratification is to identify patients at risk for adverse outcomes and to target high-risk groups for potential intervention to reduce that risk. To date, the largest organized surgical efforts have evolved through the National Surgical Quality Improvement Program (NSQIP) and the American College of Surgeons (ACS-NSQIP). In 1991, the Department of Veterans Affairs (VA) system responded to criticisms of high mortality rates by initiating a program of mandatory data collection and evaluation. The NSQIP paradigm employs local trained nurse reviewers at each site to extract individual, patient-level data. Variables collected include demographic information, baseline physiologic status, medical comorbidities, laboratory values, and surgical operative characteristics. Regression models are constructed to predict the risk of postoperative morbidity and mortality based on the collected preoperative variables (Table 15-15A,B). Ongoing system-level analysis evaluates and benchmarks performance between institutions using observed/expected (O/E) ratios for specified outcomes and allows for linkage of outcomes to process and structure of care.⁵ Success in data-driven VA process improvement initiatives has led to validation and adoption in academic and community centers.⁵

Table 15-4A Logistic Regression Models for Prediction of 30-Day Operative Mortality Using Preoperative Variables

Variable	Odds Ratio
ASA class 4/5 vs. 1/2	8.1
ASA 3 vs. 1/2	3.5
Serum albumin (per gram)	0.62
Emergency operation	2.6
Age (per year)	1
Platelet count <150,000	1.9
Disseminated cancer	2.9
Dyspnea at rest vs. none	1.6
Dyspnea with minimal exertion vs. none	1.3
DNR	3.9
BUN >40 mg/dL	1.3
Work RVU (per unit)	1.02

Derived from private sector hospitals, $n = 54,450$ patients.
 ASA, American Society of Anesthesiologist's Patient Severity Score; BUN, blood urea nitrogen; COPD, chronic obstructive pulmonary disease; DNR, do not resuscitate; RVU, relative value unit; WBC, white blood cell count K/uL.
 From Khuri SF, Henderson WG, Daley J, et al. Successful implementation of the Department of Veterans Affairs' National Surgical Quality Improvement Program in the private sector: the Patient Safety in Surgery study. *Ann Surg* 2008;248(2):329–336.

Table 15-4B Logistic Regression Models for Prediction of 30-Day Operative Morbidity Using Preoperative Variables

Variable	Odds Ratio
ASA 4/5 vs. 1/2	2.1
ASA 3 vs. 1/2	1.6
Albumin (per gram)	0.73
Work RVU (per unit)	1.05
Emergency operation	1.7
Dyspnea at rest vs. none	1.7
Dyspnea with minimal exertion vs. none	1.2
Wound infection	1.6
Patient on ventilator prior to surgery	1.9
Bleeding disorder	1.5
WBC >11,000/mL ³	1.2
Age (per year)	1.01

Derived from private sector hospitals, $n = 54,450$ patients.
 ASA, American Society of Anesthesiologist's Patient Severity Score; BUN, blood urea nitrogen; COPD, chronic obstructive pulmonary disease; DNR, do not resuscitate; RVU, relative value unit; WBC, white blood cell count K/uL.
 From Khuri SF, Henderson WG, Daley J, et al. Successful implementation of the Department of Veterans Affairs' National Surgical Quality Improvement Program in the private sector: the Patient Safety in Surgery study. *Ann Surg* 2008;248(2):329–336.

Continued development has been sponsored by the American College of Surgeons (ACS) under the ACS-NSQIP® program, combining data collection, centralized benchmarking, and regular reporting. Reports have been utilized as catalysts for institutional-level change, with substantial improvements seen following targeted quality improvement efforts.²¹ Following implementation, 66% of ACS-NSQIP hospitals saw reduced mortality rate and 82% saw reduction in complications. The annual benefit for a hospital enrolling in ACS-NSQIP has been estimated at 250 to 500 fewer complications and 12 to 36 fewer deaths.²² Observed improvements in outcomes appear to be sustained, with the magnitude of quality improvement increasing over time.²³ Of note, improvements in risk-adjusted outcomes at ACS-NSQIP hospitals were not found to differ significantly from those concurrently seen in matched non-NSQIP hospitals, suggesting that while feedback and reporting may be critical to implementing process change, they are not by themselves required to drive improvement.^{24,25}

Risk Calculators

Algorithm-based risk stratification based on large data sets is now available through the Internet or on mobile devices. In 2011, a cardiac risk calculator based on NSQIP variables compared favorably to performance of the Revised Cardiac Risk Index.²⁶ In 2013, the ACS released an online decision support tool including a perioperative risk calculator built on the NSQIP database of 1.3 million operations (www.riskcalculator.facs.org, last accessed March 30, 2016). The calculator incorporates 21 variables from the original VA NSQIP data collection and has excellent predictive performance for mortality,

morbidity, and six specific complications.²⁷ Potential criticisms of the model include dependence on American Society of Anesthesiology (ASA) Physical Status grading, imprecise definition of functional outcomes, and lack of validation outside of a NSQIP cohort²⁸; however, the ability to rapidly provide individualized patient risk estimation is an important advance. Figure 15-2A,B demonstrate an example of risk determination for a patient undergoing elective colon surgery, entering specific clinical variables and reporting specific complications in an individualized fashion. The use of mobile device decision support tools will also likely continue to increase; as an example, the Michigan Surgical Optimization Program's mobile app provides risk stratification for procedures derived from the Michigan Surgical Quality Collaborative data.

GENERAL CONCEPTS OF PREOPERATIVE EVALUATION

The setting for preoperative evaluation varies with the surgical procedure and with patient circumstances. Coordination of preoperative care at a dedicated facility has led to improved efficiency for outpatient elective surgery²⁹; however, this advantage may lessen as intensity of routine testing decreases.

Patient education remains a key aspect of the initial preoperative visit. Preoperative teaching has been shown to improve patient satisfaction and increase cooperation with postoperative recommendations.³⁰ The wealth of information available on the Internet has enabled patients to be better educated, stronger consumers and has empowered many to participate more actively in their care. Prior to the first office visit, many will have researched their disease process, surgical procedure, as well as the scorecards of the hospital and surgeon. Forward-thinking surgeons can leverage this engagement and increase the value of the face-to-face appointment by providing online teaching materials ahead of the actual office visit.

Initial evaluation includes a standard medical history and complete physical examination. The presence of allergies, current medications, chronic illnesses related and unrelated to the surgical condition, prior procedures, as well as staging and acuity of disease all contribute to the risk and benefit determinations.

Routine preoperative laboratory testing is no longer recommended. The majority of preoperative laboratory tests are rarely indicated and are of limited value.³¹ It has been demonstrated that, even when abnormal, preoperative testing often does not lead to change in perioperative management or adverse postoperative outcomes.³² Despite this, preoperative testing continues to be overused in both low risk³³ and hospital settings.³⁴

Selective laboratory testing has potential value in certain elective cases, as well as in remote telemedicine evaluations³⁵ and as part of risk assessment in elderly patients.³⁶ In all cases, testing should be based on clinical likelihood of finding and acting on abnormal results. Baseline hemoglobin should be assessed in elderly patients, patients undergoing procedures with expected major blood loss, and patients with underlying hematologic disorders. Renal function can be assessed in older patients, in younger patients with suspicion of renal disease or with associated diabetes, cardiac, vascular, or pulmonary disease, and in patients undergoing major surgery. Electrolytes, glucose, coagulation studies, and liver function tests should be performed selectively. Adjunctive cardiopulmonary evaluation should also be performed selectively.

Routine electrocardiogram (ECG) is not recommended before low-risk surgery. Patients with known coronary disease or elevated risk should be evaluated, unless the procedure itself is low risk. More invasive testing, including exercise testing, echocardiography, and cardiac catheterization should be based on the presence of symptoms, overall functional level, procedural factors, and calculated coronary risk (see Cardiac section). Routine chest x-ray, pulmonary function tests, and arterial blood gases are not indicated unless specific pulmonary symptoms are identified (see Pulmonary section).

Anesthesia

For otherwise healthy patients, selective, rather than routine, evaluation by an anesthesiologist is recommended. Use of a screening questionnaire may facilitate appropriate referral for a formal anesthesia consultation.³⁷ A nursing instrument identifying high-risk conditions (history of prior or familial anesthetic difficulty, difficult airway/limited neck motion, decreased exercise tolerance, stroke, thyroid, cardiac, asthma, and liver and renal disease) has been validated as a trigger for formal anesthesia consult.³⁸

Surgeon Adjustment of Risks

This will need to be used infrequently, but surgeons may adjust the estimated risks if they feel the calculated risks are underestimated. This should only be done if the reason for the increased risks was NOT already entered into the risk calculator.

1 - No adjustment necessary

Figure 15-2. A,B: Risk stratification: ACS-NSQIP risk calculator. (Source: www.riskcalculator.facs.org, American College of Surgeons.)

The ASA Physical Status classification (Table 15-15) addresses the overall physical status of the patient, exclusive of specific surgical considerations. Despite its relative imprecision and inconsistent application, ASA class remains strongly associated with other predictors of surgical outcomes³⁹ and continues as a standard adjunct during preoperative evaluation. The choice of anesthetic approach (local, monitored anesthesia care/sedation, neuraxial, and general) varies on the basis of the indicated procedure as well as patient considerations, with general anesthesia carrying a higher risk for pulmonary complications.⁴⁰ Systematic review suggests that the use of neuraxial blockade in surgery is associated with overall mortality reduction and decreased complications; however, it is not possible to ascertain whether these findings were due to salutary effects of regional blockade or reduction in the use of general anesthesia.⁴¹ The use of epidural anesthesia may decrease perioperative cardiac events in

patients with hip fracture and abdominal aortic aneurysm surgery,²⁸ but it is not clear that intraoperative neuraxial anesthesia universally reduces perioperative cardiac events.

Table 15-5 ASA Physical Status Classification

ASA PS Classification	Definition	Examples, Including, but Not Limited to:
ASA I	A normal healthy patient	Healthy, nonsmoking, no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Examples include (but not limited to) current smoker, social alcohol drinker, pregnancy, obesity (30 < BM < 40), well-controlled DM/HTN, mild lung disease
ASA III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases. Examples include (but not limited to) poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis, premature infant PCA <60 wks, history (>3 mo) of MI, CVA, TIA, or CAD/stents.
ASA IV	A patient with severe systemic disease that is a constant threat to life	Examples include (but not limited to) recent (<3 mo) MI, CVA, TIA, or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, sepsis, DIC, ARD, or ESRD not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Examples include (but not limited to) ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes

Surgical Procedure

Each surgical procedure carries its own set of specific risks. The overall physiologic impact varies between procedures. Procedures involving the thoracic or abdominal cavity, neurosurgery, head and neck, or vascular system carry higher risk⁴² than those limited to the extremities or subcutaneous tissue. Procedural duration, often associated with complexity and extent of resection, is also associated with increased risk.⁴⁰ The extent of surgical exposure has also been correlated with physiologic impact. Minimally invasive approaches have, in general, been associated with lower hospital length of stay, earlier return to function, reduced postoperative pain, and patient satisfaction, but in many cases encumber the risk of increased procedural duration and costs without clear mortality benefit. The urgency of the procedure affects risk assessment (Table 15-16).²⁸ Emergency surgery carries the additional challenges of life- or limb-threatening condition without the opportunity for medical optimization. The underlying processes are often catastrophic, with increased risk of infection, hemorrhage, and uncorrected physiologic derangement adding to the risk of postoperative complications⁴³ and mortality.⁴²

Disparities

Disparities in surgical outcomes based on racial and socioeconomic considerations still persist. The relative rates of postoperative complications, including respiratory failure, physiologic and metabolic derangements, are generally increased for minority patients over Caucasian patients.⁴⁴ The causes are multifactorial and, likely, patient-related factors, as well as chronic and acute health care resource availability, play a role. In a survey of the US Nationwide Inpatient Sample involving more than 3 million oncologic procedures performed between 1999 and 2009, African American, but not Hispanic patients had higher rates of vascular, wound, gastrointestinal (GI), and infectious complications when compared to white patients.⁴⁵ These variations in patterns of use suggest that unexploited opportunities may exist to reduce disparities. Cultural and economic barriers to surgical care may not be readily visible to the surgeon and should be actively considered.

Age

Patients are living longer and with more substantial comorbidities. The world’s population of people aged 60 years and older has doubled since 1980 and is forecast to reach 2 billion by 2050.⁴⁶ Demand for surgical services continues to increase faster than the rate of population growth; in 2006, surgery on elderly patients accounted for 35% of inpatient and 32% of outpatient surgical procedures.⁴⁷

Table 15-6 Procedural Urgency

Category	Characteristics	Time Frame	Example
Emergency	Immediate threat to life or limb	Typically in <6 hrs	Acute traumatic hemorrhagic shock
Urgent	Threat to life or limb	6–24 hrs	Small bowel obstruction
Time sensitive	Sufficient time for evaluation and management changes that may significantly alter outcome	1–6 wks	Oncologic surgery
Elective	Condition permits delay	Up to 1 yr	Aesthetic surgery

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.

Normal aging reduces the ability to maintain homeostatic responses in the face of acute physiologic stress⁴⁸ such as surgery. In a series of over a million Medicare patients, operative mortality for patients aged 80 years and older was observed to be more than twice that for patients aged 65 to 69 years.³ Compared with patients younger than 60 years, the risk of postoperative pulmonary complication was doubled for patients between the ages of 60 and 69 years and tripled for patients aged 70 to 79 years.⁴⁹ Optimization of surgery in the elderly requires recognition of their decreased tolerance for complications. An initial infectious or pulmonary complication is associated with significantly higher risk-adjusted failure-to-rescue rates in elderly patients when compared with younger patients.⁵⁰ Attending to prevention and early recognition of complications potentially will have great impact on these outcomes in the elderly population.

While surgical risk increases with advancing age, chronologic age alone should not be considered a contraindication to surgery in otherwise healthy patients. The association of age with other factors such as decreased functional status, an increased number of comorbidities, and more complex pharmacologic history⁵¹ renders simple conclusions unfeasible. For example, in the Revised Cardiac Risk Index model for cardiac mortality, other risk factors become more significant than age alone,⁵² while in cases of advanced age, adding age to the revised cardiac risk index (RCRI) model improves its utility for prediction.⁵³

The ACS and American Geriatric Society have published best practice Guidelines for the Optimal Preoperative Assessment of the Geriatric Patient.⁴⁷ The guidelines highlight 13 geriatric-specific domains to identify and address during the preoperative period (Table 15-7). Areas of focus include traditional preoperative evaluation (cardiopulmonary risk assessment, directed preoperative testing) and added evaluations of cognition (baseline cognition, decision-making ability, depression, risk for postoperative delirium), functional status (mobility, fall risk, and frailty), nutrition, medication (polypharmacy, alcohol/substance abuse screening), support systems (family and social), as well as discussion of goals and expectations of care.

Table 15-7 Perioperative Evaluation of the Geriatric Patient

Domain	Evaluation	Potential Intervention
Cognitive impairment and dementia	Cognitive screen: Mini-Cog, family interview	If screens positive, further evaluation by PCP, geriatrician, or mental health specialist
Decision-making capacity	The patient can: - clearly indicate treatment choice - understand relevant information - acknowledge condition, treatment options, and likely outcomes - engage in rational discussion about treatment options	If altered, discuss surrogacy for medical decision-making
Depression	Depression Screen: PHQ2	If screens positive, further evaluation by PCP, geriatrician, or mental health specialist
Risk for postoperative delirium	Risk assessment	If at risk, patients avoid benzodiazepines and antihistamines when appropriate
Alcohol and substance abuse	Modified CAGE questionnaire	- If procedure can be delayed, consider referral to substance abuse specialist - Perioperative daily MVI and thiamine
Cardiac evaluation	ACC/AHA algorithm (Algorithm 1)	If positive, consider strategies to reduce risk
Risk for pulmonary complications	NSQIP predictors (Table 15-12)	If positive, consider strategies to reduce risk
Functional status, mobility, and fall risk	Timed Up and Go Test	If abnormal
Frailty scoring	Frailty Score	If abnormal
Nutritional status	- BMI <18.5 kg/m² - Serum albumin 3.0 g/dL without renal or hepatic dysfunction - Unintentional weight lost >10%–15% in past 12 mo	If feasible, full nutritional assessment by dietician with perioperative nutritional planning
Medication management	Review medication list	Avoid polypharmacy
Counseling regarding: - advance directive and surrogate decision-making - the patient's treatment goals - the patient's expectations of surgery - the patient's family and social support system		
Appropriate preoperative diagnostic testing	Selective preoperative testing	Normal laboratory values obtained up to 4 mo preoperatively can be used safely as long as nonsubstantial interval change in clinical status has occurred

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.

Few of these domains are covered in detail during traditional preoperative surgical evaluation and further integration into routine practice is needed. Additional recommendations for geriatric patients include screening for cognitive deficits, with referral for support if screening is positive; recognition of risks for postoperative delirium (inadequate pain control, sleep deprivation), avoidance of polypharmacy (specifically avoiding drugs that contribute to delirium); encouraging early return to function with mobilization and physical therapy; and dedicating adequate time for counseling with patient, family, and surrogate decision makers.

Medical Comorbidity

5 Hypertension, coronary artery disease, diabetes, and chronic obstructive pulmonary disease (COPD) are the most frequently seen comorbidities in patients older than 70 years.⁵¹ More than 50% of these patients suffer from at least one infirmity and 30% suffer from two or more.⁵¹ As a result, polypharmacy is common. Adaptation to multiple chronic illnesses and treatments may combine to create altered physiologic responses to surgery. For example, a patient with hypertension that is well-controlled with diuretics and β -blockade may be chronically volume depleted and unable to mount cardiovascular response to further blood loss in surgery.

Obesity/Obstructive Sleep Apnea

The prevalence of adult obesity is increasing in the United States, with one-third of adults in 2009–2010 considered to be obese (body mass index [BMI] >30 kg/m²).⁵⁴ Paradoxically, in nonbariatric general surgery, a J-shaped relationship of lower mortality has been reported in overweight and moderately obese patients.⁵⁵ Nevertheless, an increased risk of postoperative complications and the need for additional operative planning is present for the bariatric patient. For this chapter, discussion centers on risk of airway difficulty and ventilation in the high BMI patient with sleep apnea.

The American Society of Anesthesiologists updated guidelines for perioperative management of patients with obstructive sleep apnea in 2014.⁵⁶ In this report, the prevalence of sleep-disordered

breathing was 9% in women and 24% in men. Patients often present without formal confirmation of the diagnosis by polysomnography. Increases in perioperative risk are noted to occur in proportion to the severity of sleep apnea.⁵⁷ Sleep apnea should be suspected in patients with history of apparent airway obstruction during sleep, BMI >35 kg/m², large neck circumference, craniofacial abnormalities, snoring, frequent arousals from sleep, and unexplained daytime somnolence or fatigue. A trial of preoperative continuous positive airway pressure may be attempted to improve nighttime airway obstruction, particularly if obstructive sleep apnea is severe. Other potential interventions include the use of mandibular advancement devices, oral appliances, and preoperative weight loss; however, evidence was judged to be insufficient to make formal recommendations.

Intraoperative considerations include choice of anesthetic technique, airway management, and patient monitoring. For appropriate procedures, regional anesthesia may be preferred over general anesthesia and continuous monitoring should be employed because of the potential for airway obstruction. Patients at risk for obstructive sleep apnea may have associated difficult airway and require special attention during induction and emergence from anesthesia. Sedation and neuromuscular blockade should be carefully monitored and fully reversed prior to extubation.

Table 15-8 METs Equivalents

METs Level	Example
>10 METs	Strenuous sports (swimming, skiing, singles tennis)
>4 METs	Climbing flight of stairs Walking up a hill Walking 4 mph on level ground
<4 METs	Slow ballroom dancing Golfing with a cart Playing a musical instrument Walking at 2–3 mph
1 MET	Eating, dressing, toileting

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.

Anemia

Anemia is independently associated with mortality in noncardiac surgery,⁵⁸ yet it is not clear that correction of anemia will alter mortality. Several randomized trials examining transfusion strategies in relatively stable patients failed to demonstrate mortality benefit with higher transfusion triggers in the ICU,⁵⁹ cardiac⁶⁰ and orthopedic surgery⁶¹ settings. At present, recommendations for perioperative transfusion are general, with consideration for higher thresholds given to patients who are symptomatic with chest pain, hypotension, or fatigue, those with known cardiac ischemia or those receiving massive transfusion for hemorrhagic shock. The use of erythropoietin stimulating agents and intravenous iron supplementation to facilitate perioperative transfusion management remains controversial,⁶² secondary to increased risk in oncologic and nonanemic patients. Current evidence does not support aggressive preoperative transfusion in patients with sickle cell disease.⁶³ Conflicting evidence has been published regarding the relationship between age of transfused cells and mortality.^{64,65}

Preoperative Functional Status

The impact of preoperative functional status has been recognized for years. Self-reported exercise intolerance (to walking four blocks or two flights of steps) is independently associated with higher risk of perioperative cardiovascular, myocardial ischemia, and neurologic events after elective major noncardiac surgery.⁶⁶ The relationship is inversely related to the total number of blocks that could be walked or flights of stairs that could be climbed. Functional ability can be quantified in terms of metabolic equivalents (METs), with 1 MET defined as the amount of oxygen consumed while sitting at rest and equal to 3.5 mL O₂ uptake/kg/min.⁶⁷ Functional status can be categorized as excellent, >10 METs; good, 7 to 10 METs; moderate, 4 to 6 METs; and poor, <4 METs. Risk is increased if unable to perform at a level of 4 METs (Table 15-8).²⁸ The ACS recommends a four-question survey of activities of daily living (ADLs) as a screen to identify unsuspected functional compromise in geriatric patients (Table 15-9A).⁶⁸

Frailty

Separate from comorbidity, elderly patients may suffer from frailty and sarcopenia.⁶⁹ In the Medicare population, additional mortality has been related to frailty⁷⁰ and the relationship has been documented in a broad population, including patients undergoing gastric surgery,⁷¹ gynecologic oncology,⁷² and cardiac surgery.⁷³ CT-based morphomic quantitation of trunk muscle volume is associated with decreases in functional performance on ADLs and independent activities as measured by the Vulnerable Elder Survey⁷⁴ as well as poorer outcomes in liver transplantation⁷⁵ and aortic surgery.⁷⁶ An operational frailty score (Table 15-9B) has been validated in elderly surgical patients and is associated with higher incidence of postoperative adverse events, increased length of hospital stay, and higher likelihood of discharge to a skilled or assisted-living facility.⁷⁷

Table 15-9A Short Simple Screen for Functional Assessment

Ask the patient the following questions: 1. Can you get out of bed or chair yourself? 2. Can you dress and bathe yourself? 3. Can you make your own meals? 4. Can you do your own shopping?
If NO to any of these questions, more in-depth evaluation should be performed, including full screening of activities of daily living and instrumental activities of daily living.
Deficits should be documented and may prompt perioperative interventions (i.e., referral to occupational therapy and/or physical therapy) and proactive discharge planning.
Adapted from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. <i>J Am Coll Surg</i> 2012;215(4):453–466.

Direction of Care

One of the most important discussions between a surgeon and the patient is the understanding of the patient’s desires regarding direction of care. There is little question of aggressive interventions for a healthy patient expecting rapid return to their preoperative level of function after elective surgery. Nevertheless, patients with severe underlying comorbidity or limited life expectancy should have the opportunity to direct overall goals of their care. One approach that incorporates principles of geriatric and palliative care is to frame surgical care for these patients in the context of time-limited trials.^{78,79} Overall prognosis, patient priorities, and specific milestones defining improvement or deterioration are discussed with the patient and family. A mutual decision for surgical care is crafted, outlining a specific time-limited trial of care and potential actions that could be undertaken at the end of the trial or in the event that complications arise. In this fashion, treatment decisions can be matched to the individual patient’s overall priorities and goals.

Table 15-9B Frailty Scoring (Operational Definition)

Criteria	Definition
Shrinkage	Unintentional weight loss ≥10 lb past year
Weakness	Decreased grip strength
Exhaustion	Self-reported poor energy and endurance
Low physical activity	Low weekly energy expenditure
Slowness	Slow walking
The patient receives 1 point for each criterion met:	
0 to 1	Not frail
2 to 3	Intermediate frail (pre-frail)
4 to 5	Frail
Adapted from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. <i>J Am Coll Surg</i> 2012;215(4):453–466.	

MEDICATION MANAGEMENT

Medication management in the perioperative period is subject to general guidelines of practice. The pharmacokinetics of drug administration, distribution, metabolism, and excretion may all be affected by surgery. Major GI procedures limit oral intake and may require alternate routes of administration. Patients receiving volume resuscitation may have increased drug volume of distribution. Fluctuations in hepatic and renal function and addition of multiple new medications may alter drug metabolism and excretion. New drug interactions may lead to increased toxicity; appropriate monitoring by drug levels may improve drug management.

A careful medication history includes prescription and nonprescription medications and nutritional and herbal supplements. Patients may be taking over-the-counter herbal supplements with substantial physiologic effects⁸⁰ but may not perceive these as being relevant to the conduct of their surgery. In one series, more than 70% of patients failed to disclose herbal medicine use during routine preoperative assessment.⁸¹ Herbal supplements are presently not subject to FDA regulation; contents may vary substantially from manufacturer to manufacturer and frank adulteration has been documented.⁸² Recommendations for commonly taken herbal supplements are summarized in [Table 15-10](#), keeping in mind that variations in supplement content may make a 7-day holding period prudent.⁸³

In the absence of clear evidence-based guidelines for perioperative medication management, a general approach is to continue drugs that would cause withdrawal within the perioperative period, and to discontinue unnecessary drugs or those with potential for adverse events, restarting them as soon as the patient condition permits.⁸³ Medications that are generally continued include β -blockers, clonidine, statins, and selective serotonin reuptake inhibitors (SSRIs). Medications that can be discontinued include diuretics, metformin, and, possibly, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) ([Table 15-11](#)).

Chronic β -blocker therapy should not be held perioperatively, as abrupt discontinuation may lead to rebound tachycardia and hypertension. Patients not previously receiving β -blockers should not have them initiated in anticipation of planned surgery, as this practice has been associated with an increase in cardiovascular events and is no longer recommended. Statins should be continued in the perioperative period when feasible. Other than β -blockers, antihypertensive medications are generally held perioperatively and should be considered individually. ACE inhibitors and ARBs are associated with perioperative hypotension⁸⁴ and renal risk. Diuretics are associated with chronic volume depletion and electrolyte abnormalities and should be held perioperatively.

Management of anticoagulation is of critical importance to surgeons and the indication for anticoagulation should be weighed against the risk of procedural bleeding. Agents should be held for the minimum interval felt safe after invasive procedure. Patients on chronic long-acting anticoagulation who are undergoing elective operation can use preoperative bridging with unfractionated or low-molecular-weight heparin prior to surgery.⁸⁵ In the emergent setting, the American College of Chest Physicians (ACCP) has published guidelines covering reversal of vitamin K competitors based on urgency of procedure and risk of life-threatening hemorrhage.⁸⁶ Reversal of newer direct thrombin inhibitors may not be possible other than waiting for drug clearance; dabigatran may be removed with dialysis; however, rivaroxaban and apixaban are highly protein bound and unlikely to be removed with this modality. In a large series, perioperative aspirin administration was associated with an increased risk of postoperative hemorrhage⁸⁷; however, a recent meta-analysis concluded that aspirin should not be stopped in the perioperative period unless bleeding risk outweighed thrombotic risk of holding the drug.⁸⁸ Dual antiplatelet therapy in the setting of coronary stent placement is specifically addressed in current American College of Cardiology/the American Heart Association (ACC/AHA) guidelines²⁸ and is discussed separately in the Cardiac section.

Table 15-10 Potential Interactions for Some Common Herbal Medicines

Common Name of Herb	Potential Interactions	Preoperative Recommendations
Echinacea	Allergic reactions; decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use, potential hepatotoxicity	No data
Ephedra	Risk for myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors	Discontinue at least 24 hrs before surgery
Dong Quai Vitamin E Evening Primrose Oil Fish Oil Feverfew Garlic Ginkgo Ginger Ginseng Guarana Goldenseal	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	Consider discontinuation 7 days before surgery (36 hrs for ginkgo)
Ginseng	Hypoglycemia; potential to increase risk for bleeding; potential to decrease anticoagulative effect of warfarin	Discontinue at least 7 days before surgery
Kava	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	Discontinue at least 24 hrs before surgery
St. John's Wort	Induction of cytochrome P-450 enzymes, with effect on cyclosporine, warfarin, steroids, protease inhibitors, and possibly benzodiazepines, calcium channel blockers, and many other drugs; decreased serum digoxin levels	Discontinue at least 5 days before surgery
Valerian	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	No data

Adapted from Ang-Lee MK, Moss J, Yuan CS. Herbal medicines and perioperative care. *JAMA* 2001;286(2):208–216; Halaszynski TM, Juda R, Silverman DG. Optimizing postoperative outcomes with efficient preoperative assessment and management. *Crit Care Med* 2004;32(4) (suppl):S76–S86.

Perioperative glucose control reduces mortality rate, hospital length of stay, and deep wound infections in cardiac surgery.⁸⁹ An adjusted dose of short-acting insulin is administered perioperatively, with intravenous insulin infusion intraoperatively if needed. The oral hypoglycemic, metformin, is associated with lactic acidosis and should be held prior to surgery.

Psychiatric medications should be managed on the basis of concern for withdrawal. Abrupt withdrawal of SSRIs may lead to nausea, vomiting, and lethargy, with symptoms seen more quickly in drugs with shorter half-life.⁹⁰ The use of SSRIs may increase the risk of bleeding, particularly when used in conjunction with nonsteroidal anti-inflammatory drugs (NSAIDs).⁸³ Benzodiazepines may be continued perioperatively. Older agents, including tricyclic antidepressants and monoamine oxidase inhibitors, may precipitate hypertensive crisis in conjunction with indirect sympathomimetics.

Patients receiving daily maintenance buprenorphine will not have sufficient surgical analgesia from usual postoperative opioid dosing regimens. Preoperative consultation with their prescriber and with the anesthesiology pain service is recommended prior to surgery. Alternative strategies, including the use of regional anesthesia and nonsteroidal and nonnarcotic regimens, may facilitate postoperative management.

Immunosuppressant medications may be reduced or discontinued prior to surgery, depending on the extent and the presence of associated infection, although a systematic review of immunomodulators in patients with inflammatory bowel disease has suggested no clear increased risk of total or infectious complications with azathioprine, cyclosporine, or infliximab.⁹¹ Steroid use carries a dose-dependent relationship with an increased risk of postoperative complications, both infectious and overall.⁹² Meta-analysis of randomized controlled trials suggests that perioperative stress dose steroids are not required unless there is dysfunction of the hypothalamic-pituitary-adrenal axis.⁹³ Anti-VEGF inhibitors are associated with an increased risk of GI perforation and delayed wound healing and their use is not recommended for 28 days before or after surgery or until surgical wounds are healed.

SPECIFIC ORGAN SYSTEM GUIDELINES

Cardiovascular

Prediction of cardiac adverse events following noncardiac surgery was pioneered in the 1970s¹ and risk stratification is most refined in this area.

Table 15-11 Common Prescription Medications That May Require Special Perioperative Management

Anticoagulants	May require reversal in acute situations May bridge therapy with unfractionated or LMW heparin
Aspirin, or dipyridamole (persantine)	In setting of PCI and prior drug eluting stent Withhold 7 days prior to surgery with increased bleeding risk May continue in select procedures
Thienopyridines (clopidogrel, ticlid)	In setting of PCI and prior drug eluting stent Withhold 7 days prior to surgery with increased bleeding risk
Glycoprotein IIb/IIIa inhibitors	In setting of PCI and prior drug eluting stent. Withhold at least 12 hrs prior to surgery, although antiplatelet effect may persist for longer
NSAIDs	Withhold prior to surgery with risk of renal complications
β-Blockers	Continue in patients already receiving drug, including day of surgery Do not begin new therapy in preoperative setting
Statins	Continue in patients already receiving drug, including day of surgery Consider initiating in patients undergoing vascular surgery
Calcium channel blockers, nitrates, most antiarrhythmics	Continue in patients already receiving drug, including day of surgery
Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers	Risk of intraoperative hypotension and renal risk, hold day of surgery
Diuretics	Renal risk, potential for hyperkalemia with potassium sparing diuretics, hold day of surgery
Metformin	Risk of lactic acidosis, withhold at least 2 days prior to surgery
Insulin	Adjust dose prior to surgery
Lithium	Potential prolongation of neuromuscular blockade, sedative action, cardiac arrhythmia withhold at least 1 day prior to surgery
Monoamine oxidase inhibitors	Potential anesthetic interactions Proceed with MAO safe anesthetic or hold for 2 wks
Selective serotonin release inhibitors	Potential bleeding complications Discontinue for 3 wks preoperatively in conjunction with psychiatry evaluation
Buprenorphine/naloxone	Preoperative weaning in conjunction with the prescribing physician Postoperative pain management may require pain/addiction specialist consultation
HIV drugs	Minimize interruptions in antiretroviral therapy Prophylaxis may vary on the basis of immune status
Steroids, immunosuppressives	Stress dose steroids indicated only if evidence of abnormal hypothalamic–pituitary–adrenal axis May be advisable to discontinue or reduce dose in presence of active infection
Oral contraceptives, conjugated estrogen	Increase hypercoagulable state Consider holding 4 wks prior to surgery; if not feasible, ensure adequate DVT prophylaxis

Risk Stratification

The current Revised Cardiac Risk Index (Table 15-12)⁵² is based on risk of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative insulin-requiring diabetes mellitus, and preoperative renal insufficiency and can be used to identify patients at higher risk for major cardiac complications (myocardial infarction [MI], pulmonary edema, ventricular fibrillation, primary cardiac arrest, complete heart block). The RCRI has been validated as a predictor of increased risk, although, disappointingly, targeted interventions in high-risk groups have not yet conclusively shown benefit. In 2007, evaluation of ACS NSQIP data in 211,410 patients demonstrated a 0.65% rate of perioperative myocardial infarction or cardiac arrest. Five predictors were identified: type of surgery, dependent functional status, abnormal creatinine, ASA class, and increasing age.²⁶ Active angina and signs of left ventricular dysfunction, such as dyspnea or worsening heart failure; syncope; significant arrhythmias; severe valvular disease; and surgery should prompt further preoperative evaluation.

The ACC and the AHA issued joint recommendations for perioperative cardiovascular evaluation and management for noncardiac surgery in 2014.²⁸ The guideline covers preoperative evaluation, risk assessment, perioperative management, and post-percutaneous coronary intervention (PCI) recommendations. Outcomes are defined in terms of a composite Major Adverse Cardiac Event (MACE), which includes death or MI. Low-risk procedures are defined as carrying a predicted MACE risk of <1% and elevated-risk procedures carrying a MACE risk of ≥1%.

Stable patients undergoing low-risk surgery and those with good exercise tolerance rarely need further cardiac evaluation. For those at higher risk, cardiology evaluation is recommended. In urgent or emergent situations where surgical intervention must proceed prior to any meaningful management changes, delay for cardiac evaluation will not be of benefit and care is focused on prompt recognition

and treatment of any perioperative events. In this paradigm, decision-making for higher-risk patients can be simplified to (1) initial determination if the procedure can be delayed to permit additional evaluation and management which could significantly alter the outcome and (2) further risk stratification and intervention if the patient condition permits. The overall ACC/AHA algorithm is reproduced in [Algorithm 15-1](#) and specific recommendations are summarized later.

Table 15-12 Revised Cardiac Risk Index

Revised Cardiac Risk Index Criteria	
High-risk surgery	
Intraabdominal	
Intrathoracic	
Suprainguinal vascular	
History of ischemic heart disease	
History of myocardial infarction	
History of current angina	
Use of sublingual nitrate therapy	
History of positive exercise test	
Pathologic Q waves on electrocardiogram	
History of congestive heart failure	
Pulmonary edema, bilateral rales or S3 gallop	
Paroxysmal nocturnal dyspnea	
CXR showing pulmonary vascular redistribution	
History of cerebrovascular disease	
History of transient ischemic attack	
History of cerebrovascular accident	
Diabetes mellitus requiring insulin therapy	
Chronic renal insufficiency, defined as a baseline creatinine level of at least 2.0 mg/dL (177 umol/L)	
Patient Receives 1 Point for Any Finding Within the 6 Major Categories	
Points	Risk of Major Cardiac Event (%)
0	0.4
1	0.9
2	6.6
3–6	11

Adapted from Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 1999;100(10):1043–1049.

Preexisting Cardiac Disease

The presence of underlying coronary artery disease is associated with postoperative MACE following noncardiac surgery. Following an acute MI, the rate of subsequent postoperative ischemia and MI decreases as the time interval to surgery increases. The risk of perioperative stroke was also increased with surgery occurring within 6 months of MI.⁹⁴ In the absence of myocardial revascularization, noncardiac surgery should be delayed for 60 days or more after acute MI. Coronary artery bypass grafting (CABG) solely to reduce perioperative risk is not recommended and should be performed only if the procedure would otherwise be indicated.

The presence of heart failure is a strong predictor of perioperative cardiac morbidity and mortality. The stability of heart failure is likely to affect outcomes, with decompensated, symptomatic heart failure identified on physical examination carrying higher risk. Preservation of left ventricular ejection fraction is an independent predictor for patients undergoing elevated-risk surgery⁹⁵ and patients with an LVEF ≤ 29% were identified as having higher risk in vascular surgery.⁹⁶

Patients with clinically suspected valvular heart disease should have review of echocardiography evaluation performed within 1 year prior to surgery or have repeat study if there has been a significant change in status or physical evaluation. Concomitant evaluation for ischemic disease should be considered. If valvular intervention is clinically indicated, intervention prior to noncardiac surgery may reduce perioperative risk.⁹⁷

Postoperative arrhythmias are common and are often triggered by the stress of surgery. Patients with heart block, implanted pacemakers, or automatic implantable cardioverter defibrillators are best served by effective communication between surgery, anesthesiology, and cardiology to optimize perioperative device management.

Although not included in most cardiac risk scoring, pulmonary hypertension is associated with increased complications⁹⁸ and patients may benefit from referral to a center with expertise for further evaluation. In a single-institution study evaluating adult patients with pulmonary hypertension undergoing anesthesia, specific risk factors were identified as associated with short-term morbidity (history of pulmonary embolism, NYHA functional class ≥ 2 , elevated-risk surgery, anesthesia > 3 hours) and postoperative mortality (pulmonary embolism, right axis deviation on ECG, right ventricular hypertrophy or right ventricular systolic pressure:systolic blood pressure > 0.66 , intraoperative vasopressor and anesthesia when nitrous oxide was not used).⁹⁹

Adult patients with congenital heart disease, when possible, should undergo preoperative evaluation in a regional center specializing in congenital cardiology.¹⁰⁰

Preoperative Testing

ECG should be considered for patients undergoing elevated risk surgery. It should also be considered in patients with a history of CHD, significant arrhythmia, peripheral arterial disease cerebrovascular disease, or significant structural heart disease, unless they are undergoing low-risk surgery.

More extensive evaluation, including exercise stress testing, assessment of left ventricular function, or coronary angiography, is performed selectively after initial risk stratification and determination of exercise tolerance. Exercise stress testing is not recommended for patients undergoing low-risk surgery or patients able to tolerate > 10 METs; patients with elevated RCRI risk, but able to tolerate > 4 METs, and patients with elevated RCRI risk, and unable to tolerate < 4 METs, but for whom cardiac evaluation will not change management. In patients with elevated RCRI risk or unable to tolerate < 4 METs in whom the opportunity exists to improve cardiac management, stress exercise testing can be useful.²⁸

Management of Antiplatelet Therapy Following Percutaneous Coronary Intervention

Recommendations following percutaneous coronary interventions are evolving and center on not just the cardiac risk, but also the risk of discontinuing dual antiplatelet therapy. Premature discontinuation of antiplatelet agents increases the risk for early and late stent thrombosis and this must be weighed against the relative risk of surgical bleeding. Dual antiplatelet therapy should not be interrupted for the initial 4 to 6 weeks after PCI. Elective surgery should be delayed at least 14 days after balloon angioplasty, 30 days after bare-metal stent implantation if antiplatelet agents are to be discontinued and 365 days after drug-eluting stent (DES) implantation, if feasible. Elective surgery may be considered earlier (180 days) following DES implantation if risk of surgical delay outweighs risk of stent thrombosis.

Management in all other situations should be determined by consensus of the surgeon, anesthesiologist, cardiologist, and patient. In patients undergoing emergent surgical procedures that mandate discontinuation of P2Y₁₂ platelet receptor inhibitors, aspirin should be continued if possible and the P2Y₁₂ platelet receptor inhibitor resumed as soon as possible following surgery ([Algorithm 15-2](#)).²⁸

Algorithm 15-1

Algorithm 15-1. Stepwise Approach to Perioperative Cardiac Assessment for CAD. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.)

Other Cardiac Medication Management

Patients on chronic β -blockade should continue treatment during the perioperative period. Prior recommendations for initiating β -blockade in patients without cardiac risk factors have been removed after meta-analysis indicated increased mortality.¹⁰¹ In patients with intermediate or high risk for myocardial ischemia, that is, three or more risk factors on RCRI, new initiation of β -blockers can be considered preoperatively but enough time should be allowed to ensure stability before surgery. Statin therapy should be continued perioperatively and new initiation can be considered for vascular¹⁰² or elevated-risk patients clinical indications. Alpha-2 blockade with clonidine should not be administered for prevention of cardiac events.¹⁰³ Aspirin, while it has a role in acute coronary syndrome and following PCI, is not indicated solely for prevention of perioperative cardiac events.⁸⁷ No benefit has been identified for perioperative nitroglycerine and routine use is not recommended.

Algorithm 15-2

Algorithm 15-2. Proposed algorithm for antiplatelet management in patients with PCI and noncardiac surgery. (From Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA Guideline on Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Noncardiac Surgery: Executive Summary: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.)

Surgical Considerations

The extent and invasiveness of the surgery must be considered, including anticipated blood loss, fluid shifts, and hemodynamic instability. In general, procedures involving extremity or noncavitary surgery pose less risk than thoracic, abdominal, or neurosurgical procedures. As hypotension and tachycardia may decrease coronary perfusion, intraoperative hemodynamic monitoring and ICU stay may be advisable for high-risk patients. Routine pulmonary artery catheter monitoring is not recommended but may be of benefit in valvular disease. Transfusion triggers for patients at risk for or experiencing active cardiac ischemia remain undefined but are generally higher than usual thresholds.

Pulmonary

Pulmonary complications following surgery are among the most frequent and costly postoperative events and lead to similar increases in morbidity, mortality, and length of stay as cardiac complications.⁴⁰ In particular, the development of pulmonary complications in the elderly may predict long-term mortality after surgery.¹⁰⁴ Age-related diminution of pulmonary function is associated with postoperative complications⁴⁰ and increasing age is an independent risk factor for postoperative pulmonary complications.⁴⁹ Other factors associated with increased risk of postoperative pulmonary complications are summarized in [Table 15-13](#).

Risk Stratification

The 2006 American College of Physicians guideline for preoperative pulmonary evaluation includes evaluation of patient-related, operative, and laboratory risk factors associated with increased risk of postoperative pulmonary complications.⁴⁹ Chronic lung disease was the most frequently identified risk factor; other patient-related factors include ASA class greater than II, increasing age, congestive heart failure, functional dependence, restrictive lung disease, and uncontrolled reactive airway disease. Operative risk factors include surgical site, duration, choice of anesthetic, emergency procedures, and

low serum albumin. Other pulmonary risk stratification scales also identified elevated blood urea nitrogen (BUN), dyspnea at rest or low levels of activity¹⁰⁵; low preoperative arterial oxygen saturation, acute respiratory infection during the previous month, age, preoperative anemia, upper abdominal or intrathoracic surgery, surgical duration of at least 2 hours, emergency surgery¹⁰⁶; and age, smoking status, airflow limitation, ASA class, hypoalbuminemia, emergency, surgery and nonlaparoscopic abdominal/cardiac and AAA repair¹⁰⁷ as risk factors for pulmonary complications.

Table 15-13 Pulmonary Complications in Noncardiac Surgery

Risk Assessment for Pulmonary Complications in Noncardiothoracic Surgery
Patient-related factors Age > 60 yrs ASA class II or greater Chronic obstructive pulmonary disease Functional dependence Congestive heart failure Dyspnea at rest or minimal exertion
Operative factors Prolonged surgery (>3 hrs) Abdominal surgery Thoracic surgery Neurosurgery Head and neck surgery Vascular surgery Emergency surgery Use of general anesthesia
Laboratory values Serum albumin <3.5 Blood urea nitrogen >40
Modified from Qaseem A, Snow V, Fitterman N, et al. Risk assessment for and strategies to reduce perioperative pulmonary complications for patients undergoing noncardiothoracic surgery: a guideline from the American College of Physicians. <i>Ann Intern Med</i> 2006;144(8):575–580; Khuri SF, Henderson WG, Daley J, et al. Successful implementation of the Department of Veterans Affairs' National Surgical Quality Improvement Program in the private sector: the Patient Safety in Surgery study. <i>Ann Surg</i> 2008;248(2):329–336.

Preoperative Evaluation

History and physical examination can be used to screen for patients requiring further assessment. Symptomatic dyspnea is a strong predictor of pulmonary complications and should be investigated further as it may signal underlying cardiopulmonary or neuromuscular dysfunction. Chronic cough or sputum production, particularly in the setting of chronic obstructive lung disease, cigarette smoking, or occupational exposures, should trigger consideration of possible associated infection. Systemic diseases may have associated pulmonary compromise. A history of restrictive chest wall disease or neuromuscular disorders may signal impaired ventilatory reserve and may impart additional risk. Physical examination findings of abnormal auscultation, scoliosis, chest wall deformity, and accessory muscle use may denote decreased functional capacity. While a history of asthma has not been confirmed to be independently associated with postoperative pulmonary complications, patients with poor control are at increased risk.¹⁰⁸

6 Routine chest radiography, pulmonary function tests, and arterial blood gases are not indicated for extrathoracic surgery⁴⁹ but may be considered in evaluation for resectional and nonresectional thoracic surgery and in patients with symptoms and undiagnosed chronic lung disease. Dyspnea on exertion should be evaluated with pulmonary function tests and chest radiography. If a cardiac etiology is suspected by history or physical examination, echocardiography can be considered. Abnormal chest radiography suggesting diffuse parenchymal disease should be investigated further. Preoperative albumin and BUN are associated with increased complications and should be obtained as part of evaluation in patients with at least one other identified risk factor.⁴⁹ Identification of patient and operative or laboratory risks should prompt further investigation.

Cigarette smoking is directly toxic to respiratory epithelium and is associated with chronic lung disease. A large systematic review concluded that cigarette smoking led to delayed healing and complications through prolonged effect on inflammatory and reparative cell functions.¹⁰⁹ A history of

cigarette smoking is associated with increased chance of major morbidity (surgical site infection, pneumonia, shock, unplanned intubation) and mortality.¹¹⁰

Benefits of smoking cessation likely increase with increased interval between stopping and surgery. Meta-analyses suggest that the effects of cigarette smoking on the tissue microenvironment and inflammatory cellular functions may be reversed within 4 weeks¹⁰⁹ and that smokers who quit more than 4 weeks before surgery have lowered risk of perioperative respiratory and wound complications.¹¹¹ Reports of increased airway reactivity during these initial weeks following smoking cessation raise concerns regarding proceeding with surgery during this period,^{112,113} although more recent studies suggest no increase in complications for shorter intervals.^{111,114} A general recommendation is that for maximum benefit, smoking should be discontinued 6 to 8 weeks preoperatively, but that stopping for any duration before surgery is beneficial.

In addition, surgery may represent an opportunity for a teachable moment for the patient's health. In a longitudinal study, patients undergoing major surgery doubled the chances of quitting.¹¹⁵ A recent Cochrane review suggested that brief and intensive interventions reduced perioperative smoking, and that more intensive structured smoking cessation interventions, including weekly preoperative counseling and nicotine replacement therapy, may be used to extend perioperative smoking cessation to long-term success.¹¹⁶

Preoperative Evaluation Prior to Lung Cancer Resection

Considerations for patients undergoing surgical treatment of lung cancer balance the intent for curative resection with concern for residual function and long-term disability following surgery. As conditions promoting the development of lung cancer, that is, cigarette smoking and occupational exposures, are also associated with intrinsic reductions in pulmonary function, the guidelines rely on physiologic testing to estimate perioperative risk as well as the effect on postoperative lung function.

In 2007, the ACCP published recommendations for evaluation of patients with lung cancer being considered for resection ([Algorithm 15-3](#)).¹¹⁷ Multidisciplinary evaluation was stressed as essential for counseling, particularly in patients with borderline function. Age alone was felt to be insufficient grounds to deny lung resection surgery. Cardiology evaluation was recommended for patients with major factors for increased perioperative cardiac risk. Initial pulmonary function testing is recommended for patients undergoing lung resection surgery and is to be performed with the patient on optimal bronchodilator therapy. Significant hypoxemia ($\text{SaO}_2 < 90\%$) but not hypercarbia ($\text{PaCO}_2 > 45$ mm Hg) was an independent risk factor for increased perioperative complications and, in its presence, physiologic testing is recommended. Additional pulmonary function testing should be prompted if forced expiratory volume in the first second of expiration (FEV_1) is $< 80\%$, if absolute values on spirometry are lower than generally accepted threshold for safe resection (1.5 L for lobectomy, 2.0 L for pneumonectomy) or if dyspnea on exertion or interstitial lung disease is suspected. Further risk stratification is based on measurement of D_{LCO} , estimation of cardiopulmonary exercise tolerance and calculation of the postoperative expected FEV_1 . In patients with borderline assessments, counseling regarding nonstandard surgery and nonoperative treatment options was recommended.

Postoperative atrial fibrillation occurs in up to 19% of patients following lung cancer resection with incidence peaking on the second postoperative day.¹¹⁸ Greater risk is present for men > 55 years of age and in the presence of a resting heart rate > 72 beats per minute and close attention should be paid to volume and electrolyte status.

Algorithm 15-3

Algorithm 15-3. Preoperative evaluation of patients with lung cancer for resection. (Adapted from Colice GL, Shafazand S, Griffin JP, et al. Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: ACCP evidenced-based clinical practice guidelines. 2nd ed. *Chest* 2007;132(3) (suppl):161S–177S.)

Surgical Considerations

Operative considerations include timing, site, duration, and choice of anesthetic. Emergency and extended (duration greater than 3 to 4 hours) procedures are associated with increased risk of pulmonary complications. In NSQIP, thoracic surgery, upper abdominal surgery, vascular surgery, and head and neck surgery have also been associated with additional risk of pulmonary complications, with thoracotomy and upper abdominal incisions associated with most marked changes in postoperative functional residual capacity. Minimally invasive and robotic approaches balance potential advantages in postoperative pain and early mobilization with the physiologic consequences of intracavitary insufflation and any additional operative time and are not always accompanied by reductions in pulmonary complications.¹¹⁹ Improving postoperative mobilization with minimally invasive approaches or intraoperative epidural anesthesia may have benefit in patients with underlying chronic lung disease.¹²⁰ For vascular surgery, endovascular approaches reduce risk of pulmonary complications compared with open surgery.¹²¹

General anesthesia-related reduction in functional residual capacity (FRC) may persist for up to 2 weeks postoperatively, with endotracheal intubation, inhalational anesthetic, and neuromuscular blockade, all potentially contributing to pulmonary dysfunction. Shorter-acting neuromuscular blocking agents may minimize perioperative weakness and promote better recovery from general anesthesia. Meta-analysis of 141 randomized controlled trials suggested that the incidence of postoperative pneumonia and respiratory failure was decreased with the use of spinal or regional anesthesia.⁴¹ Epidural anesthesia combined with general anesthesia can reduce intraoperative shunting and preemptively address postoperative pain.¹²²

Intraoperative management is directed at minimizing overzealous volume administration. Use of lung-protective tidal volume ventilation may reduce postoperative complications and intraoperative PEEP strategies are being explored in high-risk populations. Selective use of nasogastric tubes may reduce complications after abdominal surgery.¹²³ Although low serum albumin is associated with increased

risk, studies demonstrating pulmonary benefits of nutritional support and specific immunonutrition regimens are lacking.

Table 15-14 Modified Childs–Pugh–Turcotte Score

	Score		
	1 Point	2 Points	3 Points
Total serum bilirubin (umol/dL)	<3.4	3.4–5.0	>5.0
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
International normalized ratio	<1.7	1.7–2.2	>2.2
Ascites	None	Controlled with medication	Treatment refractory
Encephalopathy	None	Grades I–II or controlled with medication	Grades III–IV or treatment refractory
Sum total points for each component:			
	Total Points	Surgical Mortality	
Class A	5–6	10%	
Class B	7–9	30%	
Class C	10–15	80%

Perioperative Management

Pulmonary complications may be reduced by optimizing status of patients with preexisting lung disease, lung expansion maneuvers, and smoking cessation.

Patients with chronic lung disease should be optimized prior to elective surgery with longer-acting controller medications. Aerosolized β_2 -adrenergic receptor agonists, inhaled anticholinergics, and inhaled and systemic corticosteroids may be used to improve pulmonary function.⁴⁹ Preoperative management of poorly controlled asthma includes eliminating wheezing, cough or dyspnea, and targeting peak expiratory flows >80% of predicted or the patient's personal best.¹²⁴ Elective surgery should be delayed for signs of acute infection, including increased secretions or change in character of sputum.

Lung expansion maneuvers reduce postoperative reductions in FRC by augmenting alveolar recruitment. Common modalities, including incentive spirometry, deep-breathing exercises, and continuous positive airway pressure (CPAP), have been demonstrated to improve postoperative pulmonary outcomes.^{49,125} In patients undergoing CABG, postoperative pneumonia was reduced by 2 weeks of preoperative inspiratory muscle conditioning.¹²⁶ Concentrating education during preoperative sessions may increase patient compliance and enhance improvements in high-risk patients.^{126,127} Patients with lobar collapse or high-volume secretions may benefit from additional postural drainage and chest physiotherapy, but these maneuvers may also exacerbate bronchospasm.

Hepatic

Postoperative risk in liver disease is related to the severity of underlying liver disease and the extent of the surgical procedure.¹²⁸ Patients are living longer with chronic liver disease and they may present as relatively asymptomatic with normal liver function tests even with substantial degrees of hepatic dysfunction. In addition, occult chronic liver disease with silent cirrhosis may be present. Nonalcoholic steatohepatitis affects 2% to 5% of Americans, primarily middle-aged, overweight, or obese patients. In a series of patients undergoing bariatric surgery, 6% were found to have unsuspected cirrhosis in the setting of fatty liver.¹²⁹

The presence of cirrhosis is associated with high risk of complications and death; hepatic decompensation can follow routine surgery. While the liver is usually protected from ischemia due to dual portal and systemic blood flow, in disease states, alterations in splanchnic and autonomic vascular regulation increase vulnerability to hypoperfusion and ischemic injury. Avoidance of shock states is imperative for at-risk patients.

Risk Stratification

Overall surgical risk in cirrhotic patients appears to correlate with established scoring systems. Risk stratification extrapolates scoring based on studies in cirrhotic patients undergoing portal decompression (Modified Child–Pugh–Turcotte [CPT] score; [Table 15-14](#))^{130,131} and survival models for patients with end-stage liver disease (Model for End-Stage Liver Disease, MELD score; [Table 15-15](#)).^{132–134} Both MELD and CPT scores may correlate with postoperative mortality and are useful to guide preoperative

counseling.^{135,136}

Table 15-15 Model End-Stage Liver Disease Score

MELD score = (9.6 × log _e [creatinine mg/dL]) + (3.8 × log _e [bilirubin mg/dL]) + (11.2 × log _e [international normalized ratio]) + 6.4	
Minimum laboratory value is 1.0 (for laboratory values less than 1.0, use value of 1.0)	
Maximum creatinine is 4.0 (for creatinine >4.0, use value of 4.0)	
if patient has had dialysis twice within the previous week, use value of 4.0	
Round final score to nearest whole number	
Maximum score is 40	
90-Day Mortality for Hospitalized Patients	
MELD Score	Mortality
>40	100%
30–39	83%
20–29	76%
10–19	27%
<10	4%

Adapted from Davenport DL, Bowe EA, Henderson WG, et al. National Surgical Quality Improvement Program (NSQIP) risk factors can be used to validate American Society of Anesthesiologists Physical Status Classification (ASA PS) levels. *Ann Surg* 2006;243(5):636–641; discussion 641–644.

Historically, surgery in Child class A patients carries a mortality of 10%, Child class B, 30% and Child class C, 76% to 82%.^{137,138} The rate of postoperative complications, including liver failure, encephalopathy, bleeding infection, renal failure, hypoxia and intractable ascites, also increases with class. Poorer outcomes are associated with anemia, ascites, the presence of encephalopathy, hypoalbuminemia, hypoxia, malnutrition, concomitant infection, preoperative upper GI bleeding, intraoperative hypotension, associated renal failure or COPD, and emergency, cardiac, hepatic resection, or abdominal procedures.^{128,139} In general, mortality rates for patients undergoing emergency surgery and patients with portal hypertension are higher.

Preoperative Evaluation

History and physical examination may reveal unsuspected liver disease. History of prior hepatitis, prior anesthetic toxicity, biliary disease, hereditary metabolic disorders, bleeding, or prior alcohol or substance abuse should be sought. Physical examination may reveal stigmata of portal hypertension, including hepatomegaly, splenomegaly, ascites, abdominal wall varices, asterixis, and palmar erythema. Thrombocytopenia secondary to splenic sequestration may be an early sign of previously undiagnosed portal hypertension. If liver disease is suspected during routine preoperative evaluation, elective surgery should be deferred for further workup.¹⁴⁰

Acute conditions for which elective surgery is contraindicated include acute liver failure, acute viral hepatitis, alcoholic hepatitis, liver disease with associated acute renal failure, cardiomyopathy, hypoxemia, or severe coagulopathy.¹²⁸ Hepatic recovery may occur following an initial insult and elective surgery should be deferred for a period of several weeks to optimize the patient’s condition. For acute alcoholic hepatitis, abstinence from alcohol for 12 weeks before elective surgery has been recommended.

For patients with known chronic liver disease and cirrhosis, surgical morbidity and mortality correlate with the degree of hepatic dysfunction. Patients with compensated chronic liver disease generally tolerate most surgery well; however, patients with decompensated cirrhosis may have substantial perioperative risk proportional to the degree of hepatic dysfunction. A suggested preoperative evaluation for hepatic disease is presented in [Algorithm 15-4](#).¹⁴¹

Surgical Considerations

Intra-abdominal surgery^{142,143} and cardiac surgery¹⁴⁴ have been associated with high mortality rates in cirrhotics. In one series, patients with cirrhosis undergoing surgery had a 30-day mortality of 11.6% and an overall complication rate of 30%.¹³⁹ The most frequent complication was pneumonia, with other complications including bleeding, hepatic decompensation, sepsis, and renal failure. Umbilical hernia may be aggravated in the presence of uncontrolled ascites and nonoperative management may be

warranted. Percutaneous interventions for drainage of biliary obstruction are preferred over surgical approaches. Biliary surgery may be performed safely in Child Class A patients, following optimization in Class B patients and preferably avoided in Class C patients.¹²⁸ Formal hepatic resection in cirrhosis carries a high mortality rate that is elevated in patients with postresectional liver failure.¹⁴⁵

Perioperative Management

Perioperative management includes optimization of liver function, including management of portal hypertension, cholestasis and coagulopathy, and avoidance of further hepatic injury secondary to hypoperfusion and ischemia. Direct evidence that medical management affects subsequent outcomes is lacking in randomized studies.

Anesthetic management is directed at preservation of hepatic perfusion. The choice of inhalational agent depends on avoiding direct hepatotoxicity and depressed cardiac output; halothane is historically associated with direct injury and isoflurane and sevoflurane may be the preferred agents. Perioperative management also includes careful consideration of altered drug metabolism and toxicity. Sedative and narcotic metabolism may be reduced and careful dose titration or use of propofol may reduce oversedation.

A preoperative checklist for patients with portal hypertension has been published.¹⁴⁶ Patients with portal hypertension are at risk for bleeding from visceral and retroperitoneal varices; meticulous hemostasis is necessary and may prolong expected operative times. Impaired aldosterone metabolism leads to increased sodium conservation with subsequent volume overload. Peripheral shunting and vasodilation complicate management of acute volume shifts and intraoperative invasive hemodynamic monitoring or transesophageal echocardiography may permit goal-directed resuscitation. Surgical procedures with anticipated right-sided heart failure may worsen hepatic congestion and thus may be contraindicated. β -Blockade and octreotide may be of use in reducing splanchnic hypertension; the role of preoperative TIPS is unclear and its use cannot be routinely recommended.

Coagulopathy may exist from decreased synthetic function and may be monitored with PT and measurement and replacement of individual coagulation factors. In the presence of biliary obstruction or poor nutrition, deficiencies of vitamin K-dependent clotting factors may be reduced with oral or intravenous supplementation or factor transfusion with fresh frozen plasma or concentrated factor replacement. Enthusiasm for off-label use of Factor rVIIa to treat coagulopathy has waned in the wake of reports of adverse thrombotic events.¹⁴⁷ Thrombocytopenia from splenic sequestration may aggravate surgical bleeding and response to platelet transfusion may be blunted. Increased fibrinolysis may be present secondary to low-grade disseminated intravascular coagulation (DIC). Monitoring with thromboelastography may appropriately direct factor replacement with fresh frozen plasma, prothrombin complex concentrate or Factor rVIIa, or administration of antifibrinolytics.

Wound healing and surgical wound infection are associated with malnutrition, malignancy, and sepsis. Protein calorie malnutrition, hypomagnesemia, and hypophosphatemia may aggravate this. Empiric thiamine, folate, and multivitamin replacement should be administered. Perioperative nutritional support may be limited by intolerance of enteral protein loading and cholestatic changes from parenteral nutrition. Uncontrolled ascites can be managed with volume restriction, active diuresis once acute resuscitation is complete, and paracentesis to minimize abdominal hypertension and local wound disruption.

The development of postoperative liver dysfunction may manifest days to weeks following surgery. Encephalopathy may initially manifest as subtle cognitive changes and progress to substantial changes in mental status. Serum ammonia levels are not correlated with extent of cognitive disturbance. The European Association for the Study of the Liver (EASL) has published guidelines regarding diagnosis and management of hepatic encephalopathy.¹⁴⁸ Medical management consists of careful oversight of volume shifts, judicious sedation use, enteral lactulose titrated to 2 to 3 loose stools daily and oral antibiotics, such as rifaximin, to minimize colonic bacterial amine transformation and reduce bacterial translocation.

Patients with a history of alcohol abuse may undergo acute withdrawal following surgery. Classic delirium tremens (DTs) is seen 72 hours after cessation of alcohol use but may be seen at any time. Symptoms of autonomic instability, agitation, and delirium should be managed symptomatically with β -blockade, clonidine, and benzodiazepines. Protocolized symptom-triggered regimens are associated with lower total medication dose compared to standing regimens.¹⁴⁹ DT prophylaxis with round-the-clock medication is not indicated outside of high-risk cases or a history of prior DTs.

Algorithm 15-4. Proposed algorithm for preoperative evaluation of patients with liver disease. (Adapted from Hanje AJ, Patel T. Preoperative evaluation of patients with liver disease. *Nat Clin Pract Gastroenterol Hepatol* 2007;4(5):266–276.)

Renal

Surgery may worsen preexisting renal dysfunction. There is increasing recognition that new renal failure manifested by even small, transient increases in serum creatinine during the postoperative period is associated with later mortality.¹⁵⁰ Therefore, preoperative evaluation should be based not only on determining current status of chronic or acute renal disease but also on the potential for further deterioration.

Risk Stratification

The strongest risk factor for development of postoperative acute kidney injury is the presence of preexisting chronic renal disease.¹⁵¹ The development of postoperative renal failure is in turn strongly associated with increased mortality.^{150,152,153} A single episode of acute kidney injury (AKI) as defined by RIFLE criteria is associated with long-term mortality in proportion with the severity of injury. In a large noncardiac surgery series,¹⁵⁴ anemia (hemoglobin < 12.0 g/dL) and a decrease in postoperative hemoglobin greater than 1.1 g/dL were associated with higher risk for renal failure. Using a large intraoperative data set, risk factors for the development of acute kidney injury in noncardiac surgical patients were identified and used to model an Acute Kidney Index scoring system (Table 15-16).¹⁵³

Preoperative Evaluation

The presence of underlying renal disease should be suspected on the basis of history. Chronic renal disease in the adult population is not uncommon, with an estimated prevalence at 13%.¹⁵⁵ Common systemic conditions such as hypertension, diabetes mellitus, and arteriosclerosis may lead to end organ damage. Renal impairment must be considered in the context of the presence of associated systemic disease.

Determination of renal function is based on the glomerular filtration rate (GFR), estimated by equations such as the Cockcroft–Gault equation.¹⁵⁶ As the GFR is reduced to <30% of baseline, electrolyte, volume, and red cell homeostasis are altered. Medication excretion will be decreased and drug dosing should be titrated by levels to minimize toxicity.

Defining Acute Kidney Injury

In a noncardiac general surgical population, the incidence of postoperative renal failure may be as high as 1%.¹⁵³ The majority of perioperative studies have used differing definitions of postoperative renal failure and direct comparisons are difficult. Small increases in creatinine, as little as 0.3 mg/kg, may increase risk.¹⁵⁷ The search for a consistent definition continues. Criteria utilized in the ICU setting are being validated as predictors of renal outcomes in cardiac, general, and vascular surgery outcomes.^{150,158} In 2004, the Acute Dialysis Quality Initiative group developed the RIFLE (Risk, Injury, Failure, Loss, End-Stage) consensus definition of renal failure (Table 15-17).¹⁵⁹ Subsequent refinements

(the Acute Kidney Injury Network and Kidney Disease Improving Global Outcomes) have been proposed as an attempt to further incorporate oliguria, as well as relative and absolute changes in serum creatinine to the RIFLE framework. Promising biomarkers for predicting and measuring acute renal failure have been identified and it is likely that future definitions will incorporate these.

Prevention of Acute Kidney Injury

Strategies for prevention of postoperative renal failure include stabilization of homeostatic imbalances, maintenance of adequate renal perfusion, avoidance of intraoperative hypotension, and judicious use of nephrotoxic agents, including aminoglycosides, ace-inhibitors, intravenous contrast agents, and NSAIDs. In patients with known chronic renal disease, careful evaluation of electrolyte abnormalities, anemia, and intravascular volume should be performed.

The mainstay of prevention strategies is to ensure adequate renal perfusion by avoiding hypotension from hypovolemia. In diabetic patients receiving IV contrast dye, preemptive saline hydration reduced the risk of renal failure; the addition of prophylactic sodium bicarbonate was not demonstrably superior to saline hydration alone.¹⁶⁰

Despite extensive clinical testing, no pharmacologic intervention has been found to successfully improve postoperative renal outcomes. Preoperative statin,¹⁶¹ prophylactic or therapeutic acetylcysteine,¹⁶² ANP,¹⁶³ insulin-like growth factor¹⁶⁴ tight glycemic control, and antiplatelet drugs have all failed to show efficacy. In the POISE-2 trial, neither aspirin nor clonidine reduced the risk of renal failure in noncardiac surgery, although each drug had increased rates of complications (bleeding, hypotension) associated with higher rates of renal failure.¹⁵⁷ Calcium channel blockers have been associated with renoprotection in transplant surgery¹⁶⁵ but have been associated with increased renal failure rates after cardiac surgery.¹⁶⁶ Forced diuresis with low-dose dopamine and furosemide can maintain urinary flow but do not improve intrinsic renal function.¹⁶⁷ A recent randomized trial of fenoldopam in cardiac surgery demonstrated no reduction in need for renal replacement therapy or 30-day mortality but did show a higher incidence of hypotension.¹⁶⁸

Table 15-16 General Surgery Acute Kidney Injury Risk Index Classification System

Derivation Cohort, N = 57,080				Validation Cohort, N = 18,872		
Preoperative Risk Class	Total Patients, n	AKI Incidence, % (n)	Hazard Ratio (95% Confidence Interval)	Total Patients, n	AKI Incidence, % (n)	Hazard Ratio (95% Confidence Interval)
Class I (0–2 risk factors)	31,500	0.2 (66)	—	10,301	0.2 (25)	—
Class II (3 risk factors)	12,570	0.8 (104)	4.0 (2.0–5.4)	4,218	0.6 (32)	3.1 (1.0–5.3)
Class III (4 risk factors)	7,033	1.6 (144)	6.8 (0.0–11.5)	2,025	2.0 (53)	8.5 (5.3–13.7)
Class IV (5 risk factors)	3,015	3.3 (118)	10.1 (11.0–21.5)	1,244	3.6 (45)	15.4 (0.4–25.2)
Class V (6+ risk factors)	1,450	8.0 (120)	40.3 (34.2–62.0)	484	9.5 (40)	40.2 (26.3–70.9)
Patient receives 1 point for each Risk Factor

Diabetes mellitus, on oral or insulin therapy						

From Kheterpal S, Tremper KK, Heung M, et al. Development and validation of an acute kidney injury risk index for patients undergoing general surgery: results from a national data set. *Anesthesiology* 2009;110(3):505–515.

Perioperative Management

Preoperative hyperkalemia may exist in up to 38% of patients with chronic renal failure.¹⁶⁹ Acute ECG changes should be immediately stabilized with administration of intravenous calcium and intracellular shifts with sodium bicarbonate or insulin and glucose. Removal of excess potassium may be accomplished with exchange resins or acute dialysis.

Anemia is well tolerated in patients with chronic renal failure. Erythropoietin-stimulating agents are recommended for patients on and approaching dialysis; black box warnings have been issued for use in oncologic patients and advise against high hemoglobin targets. Associated coagulopathy related to uremic platelet dysfunction may be managed with desmopressin acetate, platelet transfusion, or dialysis.

Volume overload may accompany acute and chronic oliguric renal failure. Following surgery, volume resuscitation should be goal directed and hydroxyethyl starch¹⁷⁰ and hyperchloremic solutions should be avoided.¹⁷¹ Hyperresuscitation may result in development of abdominal compartment syndrome; if prerenal oliguria persists despite medical management, decompressive laparotomy may be required to restore renal perfusion.¹⁷²

Table 15-17 The RIFLE Classification for Acute Renal Failure

	Urine Output Criteria	GFR Criteria
Risk (R)	<0.5 mL/kg/hr × 6 hrs	Increased [creat] × 1.5, or GFR decrease of >25%
Injury (I)	<0.5 mL/kg/hr × 12 hrs	Increased [creat] × 2, or GFR decrease of >50%
Failure (F)	<0.5 mL/kg/h × 24 hrs, or anuria for 12 hrs	Increased [creat] × 3, or GFR decrease of >75%, or [creat] > 4 mg/dL
Loss (L)	NA	Persistent ARF (“F”) for > 4 wks but less than 3 mo
End-stage renal disease (E)	NA	Persistent ARF (“F”) for >3 mo

ARF, acute renal failure; [creat], Serum creatinine concentration; GFR, glomerular filtration rate; NA, not applicable.
Adapted from Kellum JA, Bellomo R, Ronco C. Classification of acute kidney injury using RIFLE: what’s the purpose?; *Crit Care Med* 2007;35(8): 1983–1984.

Once renal failure occurs, substantial alterations in drug metabolism and excretion must be considered. From an anesthetic standpoint, sedative and narcotic dosing must be adjusted for elevated half-life and prolonged neuromuscular blockade may occur with agents acting at the neuromuscular junction. Succinylcholine is contraindicated in the presence of hyperkalemia. Agents undergoing peripheral Hoffman degradation may be used preferentially in the face of renal dysfunction. Meta-analysis in cardiac surgery has suggested that the use of volatile anesthetics may also be associated with lower absolute increases in serum creatinine.¹⁷³

Renal replacement therapy is indicated emergently for correction of acidosis, symptomatic hyperkalemia, severe volume overload, or uremic pericarditis. Dialysis may be undertaken preoperatively to optimize volume and electrolyte status prior to surgery. Once GFR falls below 5 to 10 mL/min, hemodialysis is usually indicated for clearance. Continuous venovenous hemodialysis may permit volume removal in the hemodynamically unstable patient. Consideration should be given to the location of temporary dialysis access; subclavian and upper extremity access should be avoided in patients who may eventually go on to require permanent dialysis access.

ADDITIONAL CONSIDERATIONS, FUTURE DIRECTIONS

Considerable progress has been made in refining preoperative risk assessment; however, the majority of the risk factors identified to date have been nonmodifiable (i.e., age, need for emergent surgery, and type of surgery required). As electronic health data collection becomes more prevalent and facile, new predictors of surgical risk that permit targeted interventions may be uncovered and present opportunities for study.

In the meantime, the preoperative visit should continue to function as an opportunity to initiate care for patients identified as high-risk. Process of care practices with broad proven benefit can be protocolized as part of routine presurgical orders; an example would be compliance with the Surgical Care Initiative Project (SCIP) performance measures in the domains of infection prophylaxis and deep venous thrombosis (DVT) prophylaxis. Studies evaluating early “prehabilitation” or “training for surgery” for patients with functional deficits are in progress. Advance in preoperative assessment will continue to contribute to the best outcomes for surgical patients.

Chapter 16

Measuring the Quality of Surgical Care

Justin B. Dimick and John D. Birkmeyer

Key Points

- 1 Quality measures fall into three categories: structure, process, and outcomes. Healthcare structure refers to fixed attributes of the system in which patients receive care. Process of care measures are the clinical details of care provided to patients. Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient.
 - 2 Composite measures, created by combining multiple individual quality indicators, are becoming increasingly used in the assessment of surgical quality. Most existing value-based purchasing programs use composite measures of some type to assess the quality of care.
 - 3 No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in net improvement in health quality.
 - 4 It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement – raising the level of performance for all providers or (b) selective referral – directing patients to higher-quality hospitals and/or providers.
 - 5 For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes.
 - 6 With selective referral, a good measure will steer patients to better hospitals or physicians. As a basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future.
 - 7 One of the biggest limitations of surgical quality measurement is the statistical “noise” from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. An emerging technique, reliability adjustment, directly addresses this problem. This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process.
 - 8 Another significant limitation of existing approaches to surgical quality assessment is a lack of good measures of global quality. As payers and purchasers of health care move forward with value-based purchasing, there is a growing need for better composite scores. In this chapter, we discuss an emerging technique for creating empirically weighted composite measures of surgical performance.
 - 9 An emerging technique for creating empirically weighted composite measures of surgical performance is improving the quality and efficiency of surgical care. Quality measures are only useful if they inform improvement efforts. Future refinements in measurement should therefore aim to meet the diverse needs of the improvement efforts of patients, payers, and providers.
-

With growing recognition that the quality of surgical care varies widely, good measures of performance are in high demand. Patients and their families need accurate information to help them choose the safest hospitals for surgery.¹ Employers and payers need reliable measures for their value-based purchasing programs.² Motivated in part by these external pressures, clinical leaders need better measures to guide their quality improvement efforts.³

Despite a broadening array of measures, there remains considerable uncertainty about which measures are most useful.^{4,5} Current measures are remarkably heterogeneous, encompassing different elements of healthcare structure, process, and outcomes. With the proliferation of value-based purchasing, which requires a global assessment of quality, there has been a rapid growth in the use of

composite measures.⁶ Although each of these types of performance measures has strengths, each is also associated with conceptual, methodological, and/or practical problems (Table 16-1).

This chapter provides an overview of existing quality indicators followed by a review of the main strengths and limitations of each type of measure: structure, process, outcomes, and composites. The chapter then closes with recommendations for selecting the right measure and a description of emerging techniques that address some of the limitations of existing quality measures.

OVERVIEW OF CURRENT MEASURES

An ever-broadening array of performance measures has been developed for assessing surgical quality. Over the past few years, the National Quality Forum (NQF) has emerged as the leading organization endorsing quality measures. While the NQF is the central organization for evaluating candidate measures, many other organizations continue to create their own quality indicators. For example, the Center for Medicare and Medicaid Services (CMS) Surgical Care Improvement Program (SCIP), which includes process measures related to prevention of surgical site infections, postoperative cardiac events, venous thromboembolism, and respiratory complications, are routinely collected and publicly reported on the Hospital Compare website for most US hospitals.

The Agency for Healthcare Research and Quality (AHRQ) has focused on quality measures that can be used with administrative data. For example, the AHRQ maintains and distributes state and national administrative data as part of their Healthcare Cost and Utilization Project (HCUP). Processes of care are generally not available in these datasets, so the AHRQ measures focus mainly on structure (e.g., hospital volume) and outcomes (e.g., mortality rates).

Table 16-1 Examples, Strengths, and Limitations of Different Approaches to Measuring Surgical Performance

	Examples	Strengths	Limitations
Structure	Hospital or surgeon volume Surgeon specialty training	Inexpensive and readily available Strong relationship to important outcomes	Not actionable for quality improvement Not good at discriminating individual provider performance
Process	Appropriate selection, timing, and duration of antibiotic prophylaxis Use of internal mammary artery for coronary artery bypass grafting	Actionable as targets for improvement Everybody can achieve 100% compliance	Most known processes relate to secondary outcomes High-leverage processes are unknown for most procedures
Outcome	Risk-adjusted mortality Risk-adjusted morbidity	Seen as the bottom line of patient care Buy-in from providers	Sample sizes too small at individual hospitals
Composite	The Leapfrog Group's Survival Predictor STS Composite score for coronary artery bypass grafting	Addresses problems with small sample size Makes sense of multiple conflicting measures	Too broad to identify specific areas that need improvement

STS, Society of Thoracic Surgeons.

The Leapfrog Group, a coalition of large employers and healthcare purchasers, has issued perhaps the most visible set of surgical quality indicators for its value-based purchasing initiative. Although originally focused exclusively on structural measures, including volume standards, their current standards also include selected processes and risk-adjusted outcomes. More recently, the Leapfrog Group began publicly reporting a composite measure of operative mortality and hospital volume as the primary measure for their evidence-based hospital referral initiative on their website.⁷ We will discuss composite measures in detail later in this chapter.

INDIVIDUAL QUALITY MEASURES

1 Quality measures fall into three categories: structure, process, and outcomes.

Structure

Healthcare structure refers to fixed attributes of the system in which patients receive care. Many structural measures describe hospital-level attributes, such as the resources or staff coordination and organization (e.g., nurse-to-patient ratios, hospital teaching status). Other structural measures reflect

attributes of individual physicians (e.g., subspecialty board certification, procedure volume).

Strengths

Structural measures of quality have several attractive features. First, they are strongly related to patient outcomes. For example, with esophagectomy and pancreatic resection, operative mortality rates at high-volume hospitals are often 10% lower, in absolute terms, than low-volume centers.^{8,9} In some instances, structural measures such as procedure volume are more predictive of subsequent hospital performance than any known processes of care or even direct mortality measures (Fig. 16-1).

Perhaps the most important advantage of structural variables is the ease with which they can be assessed. Many can be determined using readily available sources, such as administrative billing data. Although some structural measures require surveying hospitals or providers, such data are much less expensive to collect than measures requiring detailed patient-level information.

Figure 16-1. Ability of hospital rankings based on 2003–2004 mortality rates and hospital volume to predict risk-adjusted mortality in 2005–2006. Data shown for abdominal aortic aneurysm repair (A) and pancreatic cancer resection (B). Source: National Medicare data.

Limitations

Perhaps the greatest limitation of structural measures is that they are not readily actionable. For example, a small hospital cannot readily make itself a high-volume center. Thus, while selected structural measures may be useful for selective referral initiatives, they have limited value for quality improvement purposes. Structural measures are also limited in their ability to discriminate the performance of individual providers. For example, in aggregate, high-volume hospitals have much lower mortality rates than lower-volume centers for pancreatic resection.^{8,9} However, some individual high-volume hospitals may have high mortality rates, and some low-volume hospitals may have low mortality rates.¹⁰ Although the true performance of individual hospitals is difficult to confirm empirically (for sample size reasons), this lack of discrimination is one reason structural measures are often viewed as “unfair” by many providers.

Process of Care

Process of care measures are the clinical details of care provided to patients. Although long the predominant quality indicators for medical care, their popularity in surgery is growing rapidly. Perhaps

the best example of the trend toward using process measures is the CMS's SCIP. As previously mentioned, this quality measurement initiative focuses exclusively on processes related to prevention of surgical site infections, postoperative cardiac events, venous thromboembolism, and respiratory complications.

Strengths

Since processes of care reflect the care actually delivered by physicians, they have face validity and enjoy greater buy-in from providers. They are also directly actionable and provide good substrate for quality improvement activities. Although risk adjustment may be important for outcomes, it is not required for many process measures. For example, the appropriate prophylaxis against postoperative venous thromboembolism is a widely used process measure. Since virtually all patients undergoing open abdominal surgery should be offered some form of prophylaxis, there is little need to collect detailed clinical data for risk adjustment.

Limitations

The biggest limitation of process measures is the lack of correlation between processes of care and important outcomes.⁴ There is a growing body of empirical data showing very little correlation between processes of care and important outcomes.¹¹⁻¹³ Most data come from literature on medical diagnoses, such as acute myocardial infarction. For example, the Joint Commission and CMS process measures for acute myocardial infarction explained only 6% of the observed variation in risk-adjusted mortality for acute myocardial infarction.¹²

Emerging evidence demonstrates a similar relationship for surgical process measures, especially for SCIP measures, with no measurable relationship between these widely collected process measures and important outcomes.¹³

There are several reasons why existing process measures explain very little of the variation in important surgical outcomes. First, most process measures currently used in surgery relate to secondary outcomes. While none would dismiss the value of prophylactic antibiotics in reducing risks of superficial wound infection, this process is not related to the most important adverse events of major surgery, including death.

Second, process measures in surgery often relate to complications that are very rare. For example, there is consensus that venous thromboembolism prophylaxis is necessary and important. The SCIP measures, endorsed by the NQF, include the use of appropriate venous thrombosis prophylaxis. However, pulmonary embolism is very uncommon, and improving adherence to these processes will, therefore, not avert many deaths. Until we understand which processes of care account for those adverse events leading to death, process measures will have limited usefulness in surgical quality measurement.^{4,11-14}

Outcomes

Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient. Although mortality is by far the most commonly used measure in surgery, other outcomes that could be used as quality indicators include complications, hospital readmission, and a variety of patient-centered measures of quality of life or satisfaction. The best example of this type of measurement is found in the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP).¹⁵ The ACS-NSQIP is a surgeon-led clinical registry for feeding back risk-adjusted morbidity and mortality rates to participating hospitals. After its successful implementation in Veterans Affairs (VA) hospitals, it was introduced into the private sector with good results.¹⁶ Under the guidance of the American College of Surgeons, hospital participation in the NSQIP continues to grow, with more than 400 hospitals currently participating. Several innovations to the ACS-NSQIP measurement platform in the past few years will no doubt help make the program less expensive and more useful.³

Strengths

There are at least two key advantages of outcome measures. First, outcome measures have obvious face validity, and thus are likely to get the greatest “buy-in” from hospitals and surgeons. Surgeon enthusiasm for the ACS-NSQIP and the continued dissemination of the program clearly underline this point. Second, the act of simply measuring outcomes may lead to better performance – the so-called Hawthorne effect. For example, surgical morbidity and mortality rates in VA hospitals have fallen dramatically since implementation of the NSQIP two decades ago.¹⁵ No doubt many surgical leaders at

individual hospitals made specific organizational or process improvements after they began receiving feedback on their hospitals' performance. However, it is very unlikely that even a full inventory of these specific changes would explain such broad-based and substantial improvements in morbidity and mortality rates.

Limitations

Hospital- or surgeon-specific outcome measures are severely constrained by small sample sizes. For the large majority of surgical procedures, very few hospitals (or surgeons) have sufficient adverse events (numerators) and cases (denominators) for meaningful, procedure-specific measures of morbidity or mortality. For example, Dimick et al.¹⁷ used data from the Nationwide Inpatient Sample to study seven procedures for which mortality rates have been advocated as quality indicators by the AHRQ. For six of the seven procedures, a very small proportion of US hospitals had adequate caseloads to rule out a mortality rate twice the national average (Fig. 16-2). Although identifying poor-quality outliers is an important function of outcome measurement, focusing on this goal alone significantly underestimates problems with small sample sizes. Discriminating among individual hospitals with intermediate levels of performance is even more difficult.

Another significant limitation of outcome assessment is the expense of data collection. Reporting outcomes requires the costly collection of detailed clinical data for risk adjustment. For example, it costs over \$100,000 annually for a private sector hospital to participate in the ACS-NSQIP. Because of the expense of data collection, the ACS-NSQIP currently collects data on only a sample of patients undergoing surgery at each hospital. Although this sampling strategy decreases the cost of data collection, it exacerbates the problem of small sample size with individual procedures.

COMPOSITE MEASURES

2 Composite measures, created by combining multiple individual quality indicators, are becoming increasingly used in the assessment of surgical quality.^{6,7,18} Most existing pay-for-performance efforts, including the CMS pilot, use composite measures to assess the quality of medical and surgical diagnoses. The Society of Thoracic Surgeons (STS) Measurement Taskforce has created a new composite score that combines elements of outcomes and processes of care into a single measure.¹⁸ With growing enthusiasm for this approach, the AHRQ recently published a technical review of composite measures.¹⁹

Figure 16-2. Big problems with small samples: the proportion of hospitals in the United States with sufficient caseloads (sample size) to reliably use mortality rates to measure quality.

Strengths

Composite measures have two main advantages over individual quality indicators. First, pooling multiple measures overcomes the problem with small sample sizes described earlier. Second, this approach deals with the problem of multiple conflicting measures, and simplifies quality measurement by providing a single, summary measure of performance. For example, the STS measure for cardiac surgery combines several measures of process and outcomes to create a single score with three categories: one star, two stars, and three stars.¹⁸

Limitations

Composite measures have both technical and practical limitations. Perhaps the biggest technical

challenge is weighting the input measures. Most existing composite measures are created using equal weighting, expert opinion, or the “all or none” approach. For example, the STS cardiac surgery composite score calculates a domain-specific score for morbidity, mortality, process of care, and perioperative medications, and then places equal weight on each domain.¹⁸ Unfortunately, these simplistic weighting schemes do not take into account the simple fact that some measures are more important than others. Ideally, input measures would be weighted empirically, based on how strongly they are related to important outcomes.¹⁹ An emerging technique for creating such empirically weighted composite measures of surgical performance will be discussed at the end of the chapter.^{20,21}

Composite measures also have a practical limitation. By design, composite measures reflect global performance with a procedure or specialty. It is hard to know exactly where improvement is needed with this global assessment. Thus, it is important to deconstruct the composite measures into the individual process and outcome measures. Actionable targets for improvement (e.g., high complication rates or failure to adhere to specific processes) can then be addressed.

CHOOSING THE RIGHT MEASURE

3 No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in net improvement in health quality. Thus, the direct benefits of implementing a particular measure cannot be outweighed by the indirect harms. Unfortunately, these benefits and harms are often difficult to measure and heavily influenced by the specific context and who – patients, payers, or providers – is doing the accounting. For this reason, there is no simple answer for where to “set the bar.”

4 It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement – raising the performance of all providers or (b) selective referral – directing patients to higher-quality hospitals and/or providers. Although many pay-for-performance initiatives have both goals, one often predominates. For example, the ultimate objective of the CMS’s pay-for-performance initiative with prophylactic antibiotics is improving quality at all hospitals (quality improvement). Conversely, the Leapfrog Group’s efforts in surgery are primarily aimed at getting patients to hospitals likely to have the best outcomes (selective referral).

5 For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes. Although quality improvement activities are rarely “harmful,” their major downsides relate to their opportunity cost. Initiatives hinged on bad measures divert resources (e.g., time and focus of physicians and other staff) away from more productive activities.

6 With selective referral, a good measure will steer patients to better hospitals or physicians. As a basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future. At the same time, an ideal measure would not incentivize perverse behaviors (e.g., surgeons doing unnecessary procedures to meet a specific volume standard) or negatively affect other domains of quality (e.g., patient autonomy, access, and satisfaction).

Many believe that a good performance measure must discriminate performance at the individual level. From the provider perspective in particular, a “fair” measure must reliably reflect the performance of individual hospitals or physicians. Unfortunately, as described earlier, small caseloads (and sometimes case mix variation) conspire against this objective for most procedures. Patients, however, should value information that improves their odds of good outcomes on average. Many measures meet this latter interest while failing on the former (e.g., hospital volume standards). There may be no simple solution to resolving the basic tension implied by performance measures that are unfair to providers yet informative for patients. However, it underscores the importance of being clear about both the primary purpose (quality improvement or selective referral) and whose interests are receiving top priority (provider or patient).

Figure 16-3. Variation in hospital mortality rates before and after adjusting for reliability. Twenty randomly sampled hospitals are shown. Source: National Medicare data, 2005–2006.

DEVELOPING BETTER MEASURES

7 Although great progress has been made, the science of quality measurement is in its infancy. In fact, there are solutions on the horizon for many of the limitations discussed earlier. One of the biggest limitations of surgical quality measurement is the statistical “noise” from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. In other words, it is often hard to know whether hospitals or surgeons have poor performance because they provide low-quality care or because they were unlucky. For obvious reasons, labeling surgeons and hospitals correctly is extremely important.

An emerging technique, reliability adjustment, directly addresses the problem of statistical noise.^{22,23} This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process. Essentially, it “shrinks” providers’ performance back toward average unless they deviate to such an extreme that it is safe to assume they are truly different. In this way, it gives providers the benefit of doubt. Figure 16-3 shows the risk-adjusted mortality rates for pancreatic resection in Medicare patients before and after reliability adjustment. Prior to reliability adjustment, the mortality rates varied from 0% to 100%. After reliability adjustment, the mortality rates only vary from 2% to 22%, yielding a range of performance that is clinically more realistic. Reliability adjustment is gaining popularity outside surgery (e.g., ambulatory care) and is becoming widely recognized as a valid tool for improving the accuracy of quality measurement.^{22,23}

Despite wide use in other fields, reliability adjustment is only beginning to find application in surgery. Perhaps the most prominent example is the Massachusetts state cardiac surgery report card, which publishes “smoothed” mortality rates for each hospital.²⁴ These are obtained with reliability adjustment using hierarchical modeling techniques, as described earlier. This approach was also recently applied to the morbidity and mortality rates in the ACS’s NSQIP, as described with other changes in a recent “Blueprint” for a new ACS NSQIP.³ As the advantages of this technique become more widely known, there is no doubt it will become the standard technique for reporting risk-adjusted outcomes.

8, 9 Another significant limitation of existing approaches to surgical quality assessment is a lack of good measures of global quality. As payers and purchasers of health care move forward with value-based purchasing, there is a growing need for better composite scores. Unfortunately, as discussed earlier, most approaches are not thoughtful about how they weight input measures. However, there is an emerging technique for creating empirically weighted composite measures of surgical performance.^{20,21} To create these measures, a “gold standard” quality measure is first identified (e.g., risk-adjusted mortality). The relationships between all input measures and this “gold standard” measure are then determined. A composite is then created that weights the input measures based on how reliable they are (a measure of precision) and how closely they are related to the “gold standard” outcome. Dimick et al.^{20,21} recently published the methods for creating these measures using a range of surgical procedures. They found that a composite measure of risk-adjusted mortality and hospital volume, combined with risk-adjusted mortality for other, related procedures explained a large proportion of hospital-level variation in mortality and was better at predicting future performance than any individual measure (Fig. 16-4).

Although both of these emerging techniques will enhance our ability to profile hospitals on technical

quality, we also need to develop better measures of surgical decision making. Wide geographic variations in the use of surgical procedures imply substantial underuse, misuse, and overuse. Escalating healthcare costs are at least in part due to overuse and misuse of surgical interventions. Measures of appropriateness or utilization will need to become part of our armamentarium if meaningful attempts at reducing these variations are to be made. Although appropriateness criteria have been extensively studied, there is growing consensus that they are impractical on a large scale.²⁵ The task of tabulating all of the potential scenarios in which a procedure is “appropriate” or “inappropriate” is daunting. Even when these exhaustive lists are created, reasonable clinicians may still disagree in a large proportion of cases.²⁵ Appropriateness criteria should be limited to “low-hanging fruit,” those procedures with a few, well-agreed-upon indications for operation.

Figure 16-4. Ability of various historical (2000–2001) quality indicators to forecast subsequent (2002–2003) risk-adjusted mortality with aortic valve replacement (AVR). Hospitals sorted into quintiles according to hospital volume alone, risk-adjusted mortality alone, and composite measure based on AVR mortality, AVR hospital volume, and mortality and volume with other cardiac procedures.

For the majority of procedures, however, another approach is needed. One potential approach is the measurement of utilization at the level of the Accountable Care Organization (ACO). ACOs are organization of physicians and/or hospitals that assume care for a group of patients. ACOs are felt by some health policy experts to be the right level of accountability for measuring the quality of the extended healthcare system.^{26,27} Most current ACO models fall far short of full capitation, which would undoubtedly lower rates of discretionary procedures, but there are many other ways these organizations could approach overutilization. For example, rates of surgery for each ACO could be used for public reporting, value-based purchasing, or tiered health plans. This approach would allow patients to choose hospitals based on how “aggressive” they are. Public disclosure of surgery rates would also put downward pressure on hospitals with high rates of surgery, potentially discouraging expanding capacity when it may not be necessary.

The near future will no doubt bring other major advances in the science of quality measurement. The accelerating pace of technology will surely play a role. As electronic medical records become more widely adopted, clinical data will be more easily abstracted from the patient record. Such improvements in technology will provide cost-efficient risk adjustment and more practicable approaches for assessing the adherence to important processes of care. While improvements in technology and infrastructure are of great benefit, involvement of surgeons in health services research will also be important. Studies using tools of clinical epidemiology are needed to generate evidence linking high-leverage processes of care to important outcomes. These processes of care could then be applied to existing quality measurement platforms. Surgeon-scientists with scholarship in quality improvement will be instrumental in providing these insights and leading this high-impact academic field forward.

When measuring quality, it is important to keep in mind the ultimate goal: improving the quality and efficiency of surgical care. Quality measures are only useful if they inform improvement efforts. Future refinements in measurement should therefore aim to meet the diverse needs of the improvement efforts of patients, payers, and providers. In the previous chapter, the three dominant approaches for improving surgical quality were discussed: selective referral, process compliance, and outcome measurement. These three policy approaches roughly mirror the three types of quality measures (structure, process, and outcomes), providing real-world examples of how various stakeholders weigh the pros and cons of quality indicators, and ultimately choose an assessment approach by matching the measure to the purpose.

Chapter 17

Policy Approaches to Improving Surgical Quality

John D. Birkmeyer and Justin B. Dimick

Key Points

- 1 Center of excellence programs implemented by private payers and CMS have failed to identify hospitals with superior outcomes because they rely on weak process of care measures or inaccurate, self-reported data.
 - 2 Pay-for-performance programs in surgery have been successful in increasing hospital compliance with evidence-based practice in perioperative care. It is not clear that they have improved patient outcomes, however.
 - 3 Focusing on a few discrete steps in the care of surgical patients underestimates the complexity of surgical care. Higher leverage measures, including those that reflect important aspects of surgical decision making or technical skill, are needed.
